Food-borne botulism is suspected when patients present with acute GI symptoms concurrently or just prior to the onset of a symmetric descending paralysis without sensory or central nervous system involvement. Symptoms usually begin 18 to 24 hours after ingestion and progress over days to weeks. Other symptoms can include blurred vision, photophobia (90%), dysphagia (76%), generalized weakness (58%), nausea and vomiting (56%), and dysphonia (55%). Diagnosis is made by culturing *C. botulinum* from the stool. Guillain-Barré syndrome associated with *C. jejuni* infection has been a common differential diagnosis in patients who present with these symptoms.[76] The difference lies in the onset of neurologic symptoms, which typically occur 1 to 3 weeks after the onset of *C. jejuni* infection, and the condition usually is manifested by an ascending paralysis in *C. jejuni*-associated Guillain-Barré syndrome.[77]

Treatment consists primarily of respiratory support and use of botulinum antitoxin.[75] Respiratory failure may occur prior to involvement of other upper muscle groups. If evaluation is performed within several hours of ingestion, gastric lavage or induction of vomiting is suggested. Cathartics and enemas also can be used to remove residual toxin from the bowel, but they are contraindicated in cases of ileus. Although the effectiveness of antitoxins is unknown, patients diagnosed with botulism should receive botulinum antitoxin. Botulinum antitoxin is a concentrated preparation of equine globulins obtained from horses immunized with toxins A, B, and E. Because trivalent antitoxin is equine in origin, patients should be tested for hypersensitivity before receiving the product intravenously. Other agents used experimentally as adjunctive therapy are guanidine, which antagonizes the effect of botulinum toxin at the neuromuscular junction, and 4-aminopyridine, which increases acetylcholine release. Newer and more effective methods of treatment and prevention are under development, including a botulinum toxin vaccine consisting of nontoxic botulinum fragments. Prevention always should be stressed. Botulinum toxins are heat labile and readily destroyed by 10 minutes of boiling. All home-canned foods should be processed according to directions and boiled, not just warmed, prior to consumption.

In food-borne illnesses, the cornerstone of therapy remains supportive care. ORT is preferred in replenishing and maintaining fluid and electrolyte balance, and intravenous fluid therapy should be reserved for those who are severely ill and cannot tolerate oral therapy. Antiemetics and antiperistaltic agents offer symptomatic relief, but the latter should not be given in patients who present with high fever, bloody diarrhea, or fecal leukocytes. Antimicrobial therapy is not effective in the management of *S. aureus, C. perfringens*, or *B. cereus* food poisonings. In developed countries, many of the food-borne illnesses can be prevented with proper food selection, preparation, and storage. However, in developing countries, sanitation and clean water supply are larger concerns.

ABBREVIATIONS

AIDS: acquired immunodeficiency syndrome
CDC: Centers for Disease Control and Prevention
CDI: *Clostridium difficile* infection
EAEC: enteroaggregative *Escherichia coli*
EHEC: enterohemorrhagic *Escherichia coli*

CHAPTER 123

Intraabdominal Infections

JOSEPH T. DIPIRO AND THOMAS R. HOWDIESHELL

KEY CONCEPTS

1. Most intraabdominal infections are "secondary" infections that are polymicrobic and are caused by a defect in the gastrointestinal tract that must be treated by surgical drainage, resection, and/or repair.
2. Primary peritonitis is generally caused by a single organism (*Staphylococcus aureus* in patients undergoing chronic ambulatory peritoneal dialysis [CAPD] or *Escherichia coli* in patients with cirrhosis).
3. Secondary intraabdominal infections are usually caused by a mixture of bacteria, including enteric gram-negative bacilli and anaerobes, which enhances the pathogenic potential of the bacteria.
4. For peritonitis, early and aggressive intravenous fluid resuscitation and electrolyte replacement therapy are essential. A common cause of early death is hypovolemic shock caused by inadequate intravascular volume and tissue perfusion.
5. Cultures of secondary intraabdominal infection sites are generally not useful for directing antimicrobial therapy. Treatment is generally initiated on a "presumptive" or empirical basis.
6. Antimicrobial regimens for secondary intraabdominal infections should include coverage for enteric gram-negative bacilli and anaerobes. Antimicrobials that may be used for the treatment of secondary intraabdominal infections include (a) a β-lactam–β-lactamase inhibitor combination (such as piperacillin-tazobactam), (b) a carbapenem (imipenem or meropenem), (c) quinolone (ciprofloxacin) plus metronidazole, or an aminoglycoside (gentamicin) plus clindamycin (or metronidazole).
7. Treatment of primary peritonitis for CAPD patients should include an antistaphylococcal antimicrobial such as a first-generation cephalosporin (cefazolin) or vancomycin (usually given by the intraperitoneal route).
8. The duration of antimicrobial treatment should be for a total of 5 to 7 days for most secondary intraabdominal infections.
9. Patients treated for intraabdominal infections should be assessed for the occurrence of drug-related adverse effects, particularly hypersensitivity reactions (β-lactam antimicrobials), diarrhea (most agents), fungal infections (most agents), and nephrotoxicity (aminoglycosides).

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Intraabdominal infections are those contained within the peritoneal cavity or retroperitoneal space. The peritoneal cavity extends from the undersurface of the diaphragm to the floor of the pelvis and contains the stomach, small bowel, large bowel, liver, gallbladder, and spleen. The duodenum, pancreas, kidneys, adrenal glands, great vessels (aorta and vena cava), and most mesenteric vascular structures reside in the retroperitoneum. Intraabdominal infections may be generalized or localized. They may be contained within visceral structures, such as the liver, gallbladder, spleen, pancreas, kidney, or female reproductive organs. Two general types of intraabdominal infections are discussed throughout this chapter: peritonitis and abscess. *Peritonitis* is defined as the acute inflammatory response of the peritoneal lining to microorganisms, chemicals, irradiation, or foreign-body injury. This chapter deals only with peritonitis of infectious origin.

An *abscess* is a purulent collection of fluid separated from surrounding tissue by a wall consisting of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells. These processes differ considerably in presentation and approach to treatment.

EPIDEMIOLOGY

Peritonitis may be classified as primary, secondary, or tertiary.[1–3] Primary peritonitis, also called *spontaneous bacterial peritonitis,* is an infection of the peritoneal cavity without an evident source in the abdomen. Bacteria may be transported from the bloodstream to the peritoneal cavity, where the inflammatory process begins. In secondary peritonitis, a focal disease process is evident within the abdomen. Secondary peritonitis may involve perforation of the gastrointestinal (GI) tract (possibly because of ulceration, ischemia, or obstruction), postoperative peritonitis, or posttraumatic peritonitis (blunt or penetrating trauma). Tertiary peritonitis occurs in critically ill patients and is infection that persists or recurs at least 48 hours after apparently adequate management of primary or secondary peritonitis.

1 Primary peritonitis develops in up to 10% to 30% of patients with alcoholic cirrhosis.[4] Patients undergoing chronic ambulatory peritoneal dialysis (CAPD) average one episode of peritonitis every 33 months.[5] Epidemiologic data for secondary and tertiary intraabdominal infections are limited. Secondary peritonitis may be caused by perforation of a peptic ulcer; traumatic perforation of the stomach, small or large bowel, uterus, or urinary bladder; appendicitis; pancreatitis; diverticulitis; bowel infarction; inflammatory

TABLE 123-1 Causes of Bacterial Peritonitis

Primary bacterial peritonitis
Peritoneal dialysis
Cirrhosis with ascites
Nephrotic syndrome
Secondary bacterial peritonitis
Miscellaneous causes
Diverticulitis
Appendicitis
Inflammatory bowel diseases
Salpingitis
Biliary tract infections
Necrotizing pancreatitis
Neoplasms
Intestinal obstruction
Perforation
Mechanical gastrointestinal problems
Any cause of small bowel obstruction (adhesions, hernia)
Vascular causes
Mesenteric arterial or venous occlusion (atrial fibrillation)
Mesenteric ischemia without occlusion
Trauma
Blunt abdominal trauma with rupture of intestine
Penetrating abdominal trauma
Iatrogenic intestinal perforation (endoscopy)
Intraoperative events
Peritoneal contamination during abdominal operation
Leakage from gastrointestinal anastomosis

bowel disease, cholecystitis; operative contamination of the peritoneum; or diseases of the female genital tract, such as septic abortion, postoperative uterine infection, endometritis, and salpingitis. Appendicitis is one of the most common causes of intraabdominal infection. In 1998, 278,000 appendectomies were performed in the United States for suspected appendicitis.[6]

ETIOLOGY

Primary peritonitis in adults occurs most commonly in association with alcoholic cirrhosis, especially in its end stage, or with ascites caused by postnecrotic cirrhosis, chronic active hepatitis, acute viral hepatitis, congestive heart failure, malignancy, systemic lupus erythematosus, or nephritic syndrome. It may also result from the use of a peritoneal catheter for dialysis or central nervous system ventriculoperitoneal shunting for hydrocephalus. Rarely, primary peritonitis occurs without apparent underlying disease.

Table 123–1 summarizes many of the potential causes of bacterial peritonitis. Causes include inflammatory processes of the GI tract or abdominal organs, bowel obstruction, vascular occlusions that may lead to gangrene of the intestines, and neoplasia that may cause intestinal perforation or obstruction. Other possible causes include those resulting from traumatic injuries or postoperative infections.

Abscesses are the result of chronic inflammation and may occur without preceding generalized peritonitis. They may be located within one of the spaces of the peritoneal cavity or within one of the visceral organs, and may range from a few milliliters to a liter or more in volume. These collections often have a fibrinous capsule and may take from a few weeks to years to form.

The causes of intraabdominal abscess overlap those of peritonitis and, in fact, may occur sequentially or simultaneously. Appendicitis is the most frequent cause of abscess. Other potential causes of intraabdominal abscess include pancreatitis, diverticulitis, lesions of the biliary tract, genitourinary tract infections, perforating tumors in the abdomen, trauma, and leaking intestinal anastomoses. In addition, pelvic inflammatory disease in women may lead to tuboovarian abscess. For some diseases, such as appendicitis and diverticulitis, abscesses occur more frequently than generalized peritonitis.

MICROFLORA OF THE GASTROINTESTINAL TRACT AND FEMALE GENITAL TRACT

A full appreciation of intraabdominal infection requires an understanding of the normal microflora within the GI tract. There are striking differences in bacterial species and concentrations of flora within the various segments of the GI tract (Table 123–2), and this bacterial environment usually determines the severity of infectious processes in the abdomen. Generally, the low gastric pH eradicates bacteria that enter the stomach. With achlorhydria, bacterial counts may rise to 10^5 to 10^7 organisms/mL. The normally low bacterial count may also increase by 1,000- or 10,000-fold with gastric outlet obstruction, hemorrhage, gastric cancer, and in patients receiving histamine 2 (H_2)-receptor antagonists, proton pump inhibitors, or antacids.

The biliary tract (gallbladder and bile ducts) is sterile in most healthy individuals, but in people older than 70 years of age, those with acute cholecystitis, jaundice, or common bile duct stones, it is likely to be colonized by aerobic gram-negative bacilli (particularly *Escherichia coli* and *Klebsiella* spp.) and enterococci.[7] Patients with biliary tract bacterial colonization are at greater risk of intraabdominal infection.

In the distal ileum, bacterial counts of aerobes and anaerobes are quite high. In the colon, there may be 500 to 600 different types of bacteria in stool, with concentrations often reaching 10^{11} organisms/mL and anaerobic bacteria outnumbering aerobic bacteria by more than 1,000 to 1.[2,8] In fact, up to 50% of the dry mass of stool is bacteria. Fortunately, most colonic bacteria are not pathogens because they cannot survive in environments outside the colon. Perforation of the colon results in the release of large numbers of anaerobic and aerobic bacteria into the peritoneum. The colonic flora are generally consistent unless broad-spectrum antimicrobials have been used, in which case there are increases in *Candida* or gram-negative bacteria.

TABLE 123-2 Usual Microflora of the Gastrointestinal Tract

		Approximate Concentration (Log No. Organisms/mL)	
Site	**Commonly Found Bacteria**	***Aerobes***	***Anaerobes***
Stomach[a]	*Streptococcus, Lactobacillus*	10–100	Rare
Biliary tract	Normally sterile (*Escherichia coli, Klebsiella*, or enterococci in some patients)	0	0
Proximal small bowel	*Streptococcus* (including enterococci), *E. coli, Klebsiella, Lactobacillus*, diphtheroids	100	Few
Distal ileum	*E. coli, Klebsiella, Enterobacter*, enterococci, *Bacteroides fragilis, Clostridium*, peptostreptococci	10^4–10^6	10^5–10^7
Colon	*Bacteroides* spp., peptostreptococci, *Clostridium, E. coli, Klebsiella*, enterococci, *Enterobacter*, and many others	10^5–10^8	10^9–10^{11}

[a]With achlorhydria, H_2-antagonist therapy, gastric cancer, or gastric outlet obstruction, bacterial counts may rise to 10^5/mL.

The lower female genital tract is generally colonized by a large number of aerobic and anaerobic bacteria. Anaerobes may number 10^9 organisms per milliliter and often include lactobacilli, eubacteria, clostridia, anaerobic streptococci, and, less frequently, *Bacteroides fragilis.* Aerobic bacteria most often are streptococci and *Staphylococcus epidermidis,* and these may number 10^8 organisms per milliliter.

PATHOPHYSIOLOGY

Intraabdominal infection results from bacterial entry into the peritoneal or retroperitoneal spaces or from bacterial collections within intraabdominal organs. In primary peritonitis, bacteria may enter the abdomen via the bloodstream or the lymphatic system by transmigration through the bowel wall, through an indwelling peritoneal dialysis catheter, or via the fallopian tubes in females. Hematogenous bacterial spread (through the bloodstream) occurs more frequently with tuberculosis peritonitis or peritonitis associated with cirrhotic ascites. When peritonitis results from peritoneal dialysis, skin surface flora are introduced via the peritoneal catheter. In secondary peritonitis, bacteria most often enter the peritoneum or retroperitoneum as a result of perforation of the GI or female genital tracts caused by diseases or traumatic injuries. Also, peritonitis or abscess may result from contamination of the peritoneum during a surgical procedure or following anastomotic leak.

The physiologic characteristics of the peritoneal cavity determine the nature of the response to infection or inflammation within it.[1] The peritoneum is lined by a highly permeable serous membrane with a surface area approximately that of skin. The peritoneal cavity is lubricated with less than 100 mL of sterile, clear yellow fluid, normally with fewer than 300 cells/mm^3, a specific gravity below 1.016, and protein content below 3 g/dL. These conditions change drastically with peritoneal infection or inflammation, as described below.

After bacteria are introduced into the peritoneal cavity, there is an immediate response to contain the insult. Humoral and cellular defenses respond first; then the omentum adheres to the affected area. A limited bacterial inoculum is handled rapidly by defense mechanisms, including complement activation and a leukocyte response. Under certain conditions, the bacterial insult is not contained, and bacteria disseminate throughout the peritoneal cavity, resulting in peritonitis. This is more likely to occur in the presence of a foreign body, hematoma, dead tissue, a large bacterial inoculum, continuing bacterial contamination, and contamination involving a mixture of synergistic organisms. Protein-calorie malnutrition, antecedent steroid therapy, and diabetes mellitus may also contribute to the formation of an intraabdominal abscess.

When bacteria become dispersed throughout the peritoneum, the inflammatory process involves most of the peritoneal lining. There is an outpouring into the peritoneum of fluid containing leukocytes, fibrin, and other proteins that form exudates on the inflamed peritoneal surfaces and begin to form adhesions between peritoneal structures. This process, combined with a paralysis of the intestines (ileus), may result in confinement of the contamination to one or more locations within the peritoneum. Fluid also begins to collect in the bowel lumen and wall, and distension may result.

The fluid and protein shift into the abdomen (called *third-spacing*) may be so dramatic that circulating blood volume is decreased, which causes decreased cardiac output and hypovolemic shock. Accompanying fever, vomiting, or diarrhea may worsen the fluid imbalance. A reflex sympathetic response, manifested by sweating, tachycardia, and vasoconstriction, may be evident. With an inflamed peritoneum, bacteria and endotoxins are absorbed easily into the bloodstream (translocation), and this may result in septic shock.[1] Other foreign substances present in the peritoneal cavity potentiate peritonitis. These adjuvants, notably feces, dead tissues, barium, mucus, bile, and blood, have detrimental effects on host defense mechanisms, particularly on bacterial phagocytosis.

Many of the manifestations of intraabdominal infections, particularly peritonitis, result from cytokine activity. Inflammatory cytokines, such as tumor necrosis factor-α (TNF-α), interleukin (IL) 1, IL-6, IL-8, and interferon γ (INF-γ), are produced by macrophages and neutrophils in response to bacteria and bacterial products or in response to tissue injury resulting from the surgical incision.[1,9] These cytokines produce wide-ranging effects on the vascular endothelium of organs, particularly the liver, lungs, kidneys, and heart. With uncontrolled activation of these mediators, sepsis may result (see Chap. 128).[10]

Peritonitis may result in death because of the effects on major organ systems. Fluid shifts and endotoxin may result in hypovolemic and septic shock. Hypoalbuminemia may result from protein loss into the peritoneum exacerbating intravascular volume loss. Pulmonary function may be compromised by the inflamed peritoneum, producing splinting (muscle rigidity caused by pain) that inhibits adequate diaphragmatic movement leading to atelectasis and pneumonia. Increased lung vascular permeability and resulting shunting of blood may induce onset of the respiratory distress syndrome and associated hypoxemia and hypercarbia. With fluid loss, hypotension, endotoxemia, and renal and hepatic perfusion may be compromised, and acute renal and hepatic failure are potential threats.

If peritoneal contamination is localized but bacterial elimination is incomplete, an abscess results. This collection of necrotic tissue, bacteria, and white blood cells may be at single or multiple sites and may be within one of the spaces of the peritoneal cavity or in one of the visceral organs. The location of the abscess is often related to the site of primary disease. For example, abscesses resulting from appendicitis tend to appear in the right lower quadrant or the pelvis; those resulting from diverticulitis tend to appear in the left lower quadrant or pelvis.

An abscess begins by the combined action of inflammatory cells (such as neutrophils), bacteria, fibrin, and other inflammatory mediators. Bacteria may release heparinases that cause local thrombosis and tissue necrosis or fibrinolysins, collagenases, or other enzymes that allow extension of the process into surrounding tissues. Neutrophils gathered in the abscess cavity die in 3 to 5 days, releasing lysosomal enzymes that liquefy the core of the abscess. A mature abscess may have a fibrinous capsule that isolates bacteria and the liquid core from antimicrobials and immunologic defenses.

Within the abscess, the oxygen tension is low and anaerobic bacteria thrive; thus the size of the abscess may increase because it is hypertonic, resulting in an additional influx of fluid. Hypertonicity promotes the formation of bacterial L forms, which are resistant to antimicrobial agents that disrupt cell walls. Abscess formation may continue and mature for long periods of time and may not be readily evident to either patient or physician. In some instances, the abscess may resolve spontaneously, and, infrequently, it may erode into adjacent organs or rupture and cause diffuse peritonitis. If the abscess erodes through the skin, it may result in an enterocutaneous fistula, connecting bowel to skin, or in a draining sinus tract.

The overall outcome from an intraabdominal infection depends on five key factors: inoculum size, virulence of the contaminating organisms, the presence of adjuvants within the peritoneal cavity that facilitate infection, the adequacy of host defenses, and the adequacy of initial treatment.[11]

MICROBIOLOGY OF INTRAABDOMINAL INFECTION

❷ Primary bacterial peritonitis is often caused by a single organism. In children, the pathogen is usually group A *Streptococcus*, *E. coli,*

Streptococcus pneumoniae, or *Bacteroides* species.[12] When peritonitis occurs in association with cirrhotic ascites, *E. coli* is isolated most frequently. Other potential pathogens are: *Haemophilus pneumoniae, Klebsiella, Pseudomonas*, anaerobes, and *S. pneumoniae*.[13] Occasionally, primary peritonitis may be caused by *Mycobacterium tuberculosis.* Peritonitis in patients undergoing peritoneal dialysis is caused most often by common skin organisms, such as coagulase-negative staphylococci, *Staphylococcus aureus*, streptococci, and enterococci. Gram-negative bacteria associated with peritoneal dialysis infections include *E. Coli, Klebsiella*, and *Pseudomonas*.[5] Mortality from primary peritonitis caused by gram-negative bacteria is much greater than that from gram-positive bacteria.[14]

3 Because of the diverse bacteria present in the GI tract, secondary intraabdominal infections are often polymicrobial.[2] The mean number of different bacterial species isolated from infected intraabdominal sites ranged from 2.9 to 3.7, including an average of 1.3 to 1.6 aerobes and 1.7 to 2.1 anaerobes.[15,16] With proper anaerobic specimen collection, anaerobic organisms are isolated in most patients. In one report of patients with gangrenous and perforated appendicitis, an average of 10.2 different organisms was isolated from each patient, including 2.7 aerobes and 7.5 anaerobes.[17] Purely aerobic or anaerobic infections are uncommon, as are infections caused by fungi. Table 123–3 gives the frequencies with which specific bacteria were isolated from patients with peritonitis and other intraabdominal infections.[3,18] Nosocomial infections tend to have a more diverse array of pathogens and higher likelihood of multidrug resistance compared with isolates from community-acquired infections.[18] *E. coli, Streptococcus* spp., and *Bacteroides* spp. were isolated most often from the infection site, as well as from blood cultures. In patients diagnosed with severe infections, the pattern of bacterial isolates may change and commonly includes *Candida*, enterococci, Enterobacteriaceae, and *S. epidermidis.*

Visceral organ abscesses differ in character from the typical intraabdominal abscess. Hepatic abscesses may be polymicrobial (involving *E. coli, Klebsiella*, and anaerobes) or occasionally may be caused by amoeba.[8] Pancreatic abscesses are often polymicrobial, involving enteric bacteria that ascend through the biliary system. Splenic abscesses usually result from hematogenous dissemination of bacteria, such as *E. coli, S. aureus*, *Proteus mirabilis, Enterococcus,* and *K. pneumoniae*, as well as anaerobes.[8] Pelvic inflammatory disease is associated initially with *Neisseria gonorrhoeae* or *Chlamydia trachomatis.* However, tuboovarian abscesses are usually polymicrobial, having a mix of gram-positive and gram-negative aerobes and anaerobes.

TABLE 123-3 Pathogens Isolated from Patients with Intraabdominal Infection

	Secondary Peritonitis[3]	Community-Acquired Infection[18]	Nosocomial Infection[18]
Gram-negative bacteria			
Escherichia coli	32–61%	29%	22.5%
Enterobacter	8–26%	5.2%	8.0%
Klebsiella	6–26%	2.8%	4.5%
Proteus	4–23%	1.7%	2.4%
Gram-positive bacteria			
Enterococci	18–24%	10.6%	18%
Streptococci	6–55%	13.7%	10%
Staphylococci	6–16%	3.1%	4.8%
Anaerobic bacteria			
Bacteroides	25–80%	13.7%	10.3%
Clostridium	5–18%	3.5%	3.4%
Fungi	2–5%	3%	4%

BACTERIAL SYNERGISM

The size of the bacterial inoculum and the number and types of bacterial species present in intraabdominal infections influence patient outcome. The combination of aerobic and anaerobic organisms appears to increase the severity of infection greatly. In animal studies, combinations of aerobic and anaerobic bacteria were much more lethal than infections caused by aerobes or anaerobes alone.

Facultative bacteria may provide an environment conducive to the growth of anaerobic bacteria.[2] Although many bacteria isolated in mixed infections are nonpathogenic by themselves, their presence may be essential for the pathogenicity of the bacterial mixture.[4] The role of facultative bacteria in mixed infections can include (a) promotion of an appropriate environment for anaerobic bacterial growth through oxygen consumption, (b) production of nutrients necessary for anaerobes, and (c) production of extracellular enzymes that promote tissue invasion by anaerobes.

Rat models of intraabdominal infection demonstrate that uncontrolled infection with an implanted mix of aerobes and anaerobes leads to a two-stage (biphasic) infectious process. There is an early peritonitis phase with a high mortality rate and isolation of *E. coli* from blood and a late abscess formation phase in all survivors with isolation of anaerobes such as *B. fragilis* and *Fusobacterium varium*. These experiments and others support the concept that aerobic enteric organisms and anaerobes are pathogens in intraabdominal infection. Aerobic bacteria, particularly *E. coli*, appear responsible for the early mortality from peritonitis, whereas anaerobic bacteria are major pathogens in abscesses, with *B. fragilis* predominating.[19]

Enterococcus can be isolated from many intraabdominal infections in humans, but its role as a pathogen is not clear. Enterococcal infection occurs more commonly in postoperative peritonitis, in the presence of specific risk factors indicating failure of the host's defenses (immunocompromised patients), or with the use of broad-spectrum antibiotics.[20,21]

CLINICAL PRESENTATION

Intraabdominal infections have a wide spectrum of clinical features often depending on the specific disease process, the location and magnitude of bacterial contamination, and concurrent host factors. Peritonitis is usually recognized easily, but intraabdominal abscess may often continue for considerable periods of time, either going unrecognized or being attributed to an unrelated disease process. Patients with primary and secondary peritonitis present quite differently (Table 123–4).[1]

Primary peritonitis can develop over a period of days to weeks and is usually a more indolent process than secondary peritonitis. The first sign of peritonitis may be a cloudy dialysate in patients undergoing peritoneal dialysis or worsening encephalopathy in a cirrhotic patient.

The patient with generalized bacterial peritonitis presents most often in acute distress. The patient lies still, usually on his or her back, possibly with the hips slightly flexed. Any movement of the patient, including rocking the bed or breathing, worsens the generalized abdominal pain.

If peritonitis continues untreated, the patient may experience hypovolemic shock from third-space fluid loss into the peritoneum, bowel wall, and lumen. This may be accompanied by sepsis because the inflamed peritoneum absorbs bacteria and toxins into mesenteric blood vessels and lymph nodes, initiating production of inflammatory cytokines. Hypovolemic shock is the major factor contributing to mortality in the early stage of peritonitis.

Intraabdominal abscess may pose a difficult diagnostic challenge because the symptoms are neither specific nor dramatic. The patient may complain of abdominal pain or discomfort, but these

TABLE 123-4 Clinical Presentation of Peritonitis

Primary Peritonitis
General
The patient may not be in acute distress, particularly with peritoneal dialysis.
Signs and symptoms
The patient may complain of nausea, vomiting (sometimes with diarrhea), and abdominal tenderness.
Temperature may be only mildly elevated or not elevated in patients undergoing peritoneal dialysis.
Bowel sounds are hypoactive.
The cirrhotic patient may have worsening encephalopathy.
Cloudy dialysate fluid with peritoneal dialysis.
Laboratory tests
The patient's white blood cell (WBC) count may be only mildly elevated.
Ascitic fluid usually contains greater than 300 leukocytes/mm^3, and bacteria may be evident on Gram stain of a centrifuged specimen.
In 60–80% of patients with cirrhotic ascites, the Gram stain is negative.
Other diagnostic tests
Culture of peritoneal dialysate or ascitic fluid should be positive.
Secondary Peritonitis
Signs and symptoms
Generalized abdominal pain
Tachypnea
Tachycardia
Nausea and vomiting
Temperature is normal initially then increases to 37.7°C to 38.8°C (100°F to 102°F) within the first few hours and may continue to rise for the next several hours
Hypotension and shock if volume is not restored
Decreased urine output due to dehydration
Physical examination
Voluntary abdominal guarding changing to involuntary guarding and a "board-like abdomen"
Abdominal tenderness and distension
Faint bowel sounds that cease over time
Laboratory tests
Leukocytosis (15,000–20,000 WBC/mm^3, with neutrophils predominating and an elevated percentage of immature neutrophils (bands)
Elevated hematocrit and blood urea nitrogen because of dehydration
Patient progresses from early alkalosis because of hyperventilation and vomiting to acidosis and lactic acidemia
Other diagnostic tests
Abdominal radiographs may be useful because free air in the abdomen (indicating intestinal perforation) or distension of the small or large bowel is often evident.

symptoms are not reliable. Fever is usually present; often it is low grade, but it may be high, with a spiking pattern. The patient may have a paralytic ileus and abdominal distension. The abdominal examination is unreliable; tenderness and pain may be present, and a mass may be palpated.

Peritonitis may result from an abscess that ruptures, spreading bacteria and toxins throughout the peritoneum. In other patients, the entry of bacterial toxins into the systemic circulation from the abscess may lead to sepsis and progressive multisystem organ failure (e.g., renal, hepatic, pulmonary, or cardiovascular).

Laboratory studies are not generally helpful in the diagnosis of intraabdominal abscess, although most patients will have leukocytosis. Some patients may have positive blood cultures, whereas others, particularly diabetics, may have hyperglycemia. The finding of *Bacteroides* or any two enteric bacteria in the bloodstream is often indicative of an intraabdominal infectious process.

Radiographic methods are used to make the diagnosis of an intraabdominal abscess. Plain radiographs may show air–fluid levels or a shift of normal intraabdominal contents by the abscess mass. GI contrast studies may also demonstrate this displacement of abdominal structures. Both of these modalities provide indirect evidence of abscess presence but are not generally helpful in precisely locating the abscess.

Ultrasound is a frequent first diagnostic method used when an intraabdominal abscess is suspected. The procedure may be done at the bedside, which is particularly helpful when the patient is in the intensive care unit.

Computed tomographic (CT) scanning is frequently used to evaluate the abdomen for the presence of an abscess and is the imaging modality of greatest value. An oral radiocontrast agent should be given to allow differentiation of the abscess from the bowel. Intravenous radiocontrast material will be taken up preferentially in the wall of the abscess, creating a unique radiographic appearance, so-called rim enhancement.

Magnetic resonance imaging is used infrequently to locate an intraabdominal abscess, particularly in the retroperitoneum, but this modality offers no significant advantage when compared with CT scanning.

Radioactive isotope imaging with ^{67}Ga citrate-, ^{99m}Tc-, or ^{111}In-labeled leukocytes may also be used.[22] These studies require long preparation and image acquisition and are not used routinely unless CT scanning fails to demonstrate a suspected abscess.

Intraabdominal infection caused by disease processes at specific sites often produces characteristic manifestations that are helpful in diagnosis. For example, a patient with diverticulitis may exhibit stabbing left-lower-quadrant abdominal pain and constipation. Fever and leukocytosis are frequently present, and a tender mass is sometimes palpable. With appendicitis, the findings may be inconsistent, but many patients have a sudden onset of periumbilical or epigastric pain that is usually colicky and later shifts to the right lower quadrant. The location of pain may vary because the appendix can be in many locations (e.g., retrocecal or pelvic) in the abdomen. A mass may be palpable on abdominal, pelvic, or rectal examination. The patient's temperature is generally mildly elevated early and then increases. If perforation and peritonitis occur, findings would include diffuse abdominal pain, rigidity, and sustained fever. More often, however, appendiceal perforation results in a local abscess.

TREATMENT

Intraabdominal Infections

DESIRED OUTCOME

The primary goals of treatment are correction of the intraabdominal disease processes or injuries that have caused infection and the drainage of purulent collections (abscesses). A secondary objective is to achieve a resolution of infection without major organ system complications (pulmonary, hepatic, cardiovascular, or renal failure) or adverse drug effects. Ideally, the patient should be discharged from the hospital after treatment with full function for self-care and routine daily activities.

GENERAL APPROACH TO TREATMENT

The treatment of intraabdominal infection most often requires hospitalization and the coordinated use of three major modalities: (a) prompt drainage of the infected site, (b) hemodynamic resuscitation and support of vital functions, and (c) early administration of appropriate antimicrobial therapy to treat infection not eradicated by surgery.[2]

Antimicrobials are an important adjunct to drainage procedures in the treatment of secondary intraabdominal infections; however, the use of antimicrobial agents without surgical intervention is usually inadequate. For most cases of primary peritonitis, drainage

procedures may not be required, and antimicrobial agents become the mainstay of therapy.

4 In the early phase of serious intraabdominal infections, attention should be given to the maintenance of organ system functions. With generalized peritonitis, large volumes of intravenous (IV) fluids are required to restore vascular volume, to improve cardiovascular function, and to maintain adequate tissue perfusion and oxygenation. Adequate urine output should be maintained to ensure adequate resuscitation and proper renal function. Respiratory function can be assisted by a variety of methods, including oxygen therapy, pulmonary physiotherapy, and ventilatory support in severely ill patients. Often the critically ill patient with intraabdominal infection will require intensive care management, particularly if there is cardiovascular or respiratory instability. Also, isolation procedures may be required if the infectious process poses a threat to other hospitalized patients.

An additional important component of therapy is nutrition. Intraabdominal infections often directly involve the GI tract or disrupt its function (paralytic ileus). The return of GI motility may take days, weeks, and, occasionally, months. In the interim, enteral or parenteral nutrition as indicated facilitates improved immune function and wound healing to ensure recovery.

NONPHARMACOLOGIC TREATMENT

Drainage Procedures

Primary peritonitis is treated with antimicrobials and rarely requires drainage. Secondary peritonitis requires surgical correction of the underlying pathology. The drainage of the purulent material is the critical component of management of an intraabdominal abscess. Without adequate drainage of the abscess, antimicrobial therapy and fluid resuscitation can be expected to fail.

Secondary peritonitis is treated surgically; this is often called *source control*, which refers to all the physical measures undertaken to eradicate the focus of infection.[2,23] At the time of laparotomy (surgical opening and exploration of the abdomen) attempts are made to correct the cause of the peritonitis. This may include patching a perforated ulcer with omentum, removal of a segment of perforated colon, or excision of a portion of gangrenous small intestine. Also, the surgeon may elect to leave the abdomen open after the laparotomy, plan a re-laparotomy at a later time regardless of the patient's condition, or, perform re-laparotomy if the patient develops reinfection.[23] The goal of all these procedures is to repair or remove the inflamed or gangrenous viscus and to prevent further bacterial contamination. The presence of active inflammation increases the difficulty of the surgical procedure, which results in a higher morbidity and mortality rate than if the same procedures were performed in an elective setting without inflammation.

The presence of active inflammation may make it technically impossible to perform the definitive surgical procedure. In this situation, attempts are made to provide drainage of the infected or gangrenous structures. If an intraabdominal abscess, separate from any intraabdominal organ, is discovered during an exploratory laparotomy, it may be debrided, excised, or drained. If the intraabdominal abscess involves an abdominal structure, then a resection of part or all of that organ may be required. An example of this situation is an abscess associated with diverticular disease of the colon. Management may include drainage of the abscess and resection of the involved part of the colon. All foreign material, necrotic tissue, feces, blood, or pus should be removed from the operative field, and the peritoneum should be copiously irrigated with 0.9% sodium chloride to decrease the concentrations of bacteria or other noxious substances.

After an abscess is located, it must be drained. This may be performed surgically or with percutaneous, image-guided techniques.[24] Typically, image-guided techniques employ ultrasonography or CT scanning. The management of an intraabdominal abscess with percutaneous catheter drainage may be sufficient to resolve the infection. Some patients may require a subsequent procedure to treat the underlying gastrointestinal conditions; however, a significant advantage is obtained by first draining the abscess percutaneously. This allows the surgical procedure to be performed on a patient who is no longer suffering the systemic manifestations of uncontrolled infection. Drainage techniques may be performed using endoscopy or laparoscopy. These minimal-access techniques may offer advantages when compared with traditional surgery but will probably be used less often than radiologically assisted percutaneous drainage techniques.

The most valuable microbiologic information may be obtained at the time of percutaneous or operative abscess drainage. If pus or fluid is found that is believed to be infected, it is best to aspirate 2 to 3 mL into a syringe, remove any air, and tightly cap the syringe. The specimen should be taken promptly to the microbiology laboratory, where a Gram stain should be performed immediately and cultures prepared for identification of aerobic and anaerobic bacteria. If no fluid is available for collection, culture swab devices may be applied to the infected area; however, anaerobic organisms often are not isolated from swabs.

Fluid Therapy

4 Aggressive fluid repletion and management are required for successful treatment of intraabdominal infections. Fluid therapy is instituted for the purposes of achieving or maintaining proper intravascular volume to ensure adequate cardiac output, tissue perfusion, and correction of acidosis. Loss of fluid through vomiting, diarrhea, or nasogastric suction contributes to dehydration. Intravascular volume can be assessed by blood pressure and heart rate but more accurately by measurement of central venous pressure, pulmonary capillary wedge pressure, or urinary output. When a contracted vascular volume is accompanied by hemorrhage, the initial hematocrit may be normal, but if there is no associated hemorrhage, the hematocrit is usually elevated as an indication of hemoconcentration. Urine output should be monitored continuously in severely ill patients by use of a urinary bladder catheter, quantitated hourly, and should equal or exceed 0.5 mL/kg of body weight per hour.

In patients with peritonitis, hypovolemia is often accompanied by acidosis, so a reasonable IV fluid would be lactated Ringer's solution, which contains the bicarbonate precursor lactate, as well as sodium, chloride, potassium, and calcium. In the initial hour of treatment, large volumes of solution may be required to restore intravascular volume. Thereafter, fluids may be required at a rate of 1 L/h. Maintenance fluids should be instituted (after intravascular volume is restored) with 0.9% sodium chloride and potassium chloride (20 mEq/L) or 5% dextrose and 0.45% sodium chloride with potassium chloride (20 mEq/L). The administration rate should be based on estimated daily fluid loss through urine and nasogastric suction, including 0.5 to 1.0 L for insensible fluid loss. Potassium would not be included routinely if the patient is hyperkalemic or has renal insufficiency.

In patients with significant blood loss, blood transfusion may be indicated. This is generally in the form of packed red blood cells. The criteria for blood transfusion are controversial, but a hematocrit of 25% is generally accepted. In the individual patient, the decision is often determined by the overall clinical status and the ability of the patient to compensate for the reduction in oxygen-carrying capacity associated with an acute anemia. Additional blood component therapy with fresh-frozen plasma or platelets is also based on the needs of the individual patient. Aggressive fluid therapy must often be continued in the postoperative period because fluid will continue to sequester in the peritoneal cavity, bowel wall, and lumen.

PHARMACOLOGIC TREATMENT

Antimicrobial Therapy

The goals of antimicrobial therapy are (a) to control bacteremia and prevent the establishment of metastatic foci of infection, (b) to reduce suppurative complications after bacterial contamination, and (c) to prevent local spread of existing infection. After suppuration has occurred (e.g., an abscess has formed), a cure by antibiotic therapy alone is very difficult to achieve; antimicrobials may serve to improve the results obtained with surgery.

5 An empirical antimicrobial regimen should be started as soon as the presence of intraabdominal infection is suspected. Therefore, antibiotics are usually initiated after culture specimens are collected but before identification of the infecting organisms is complete. Therapy must be initiated based on the likely pathogens. Predominant pathogens, as discussed in the preceding section, vary depending on the site of intraabdominal infection and the underlying disease process. Table 123–5 lists the likely pathogens against which antimicrobial agents should be directed.

Antimicrobial Experience Many studies have been conducted evaluating or comparing the effectiveness of antimicrobials for the treatment of intraabdominal infections. Substantial differences in patient outcomes from treatment with a variety of agents have not generally been demonstrated.[25]

Important findings from over 20 years of clinical trials regarding selection of antimicrobials for intraabdominal infections are the following:

- Antimicrobial regimens used for secondary infections should cover a broad spectrum of aerobic and anaerobic bacteria from the gastrointestinal tract. Treatment of healthcare-associated infections should consider the high prevalence of resistant bacterial and fungal pathogens.
- Single-agent regimens (such as antianaerobic cephalosporins, extended-spectrum penicillins with β-lactamase inhibitors, and carbapenems) are as effective as combinations of aminoglycosides with antianaerobic agents. This is also true for antimicrobial treatment of acute bacterial contamination from penetrating abdominal trauma.[26,27]
- Clindamycin and metronidazole appear to be equivalent in efficacy when combined with agents effective against aerobic gram-negative bacilli (gentamicin or aztreonam).
- For most patients, antimicrobial treatment can be completed orally with amoxicillin-clavulanate or the combination of ciprofloxacin and metronidazole.
- Five to seven days of antimicrobial treatment is sufficient for most uncomplicated intraabdominal infections of mild to moderate severity.

TABLE 123-5 Likely Intraabdominal Pathogens

Type of Infection	Aerobes	Anaerobes
Primary bacterial peritonitis		
Children (spontaneous)	Group A *Streptococcus*, *E. coli*, pneumococci	–
Cirrhosis	*E. coli*, *Klebsiella*, pneumococci (many others)	–
Peritoneal dialysis	*Staphylococcus*, *Streptococcus*, *E. coli*, *Klebsiella*, *Pseudomonas*	–
Secondary bacterial peritonitis		
Gastroduodenal	*Streptococcus*, *E. coli*	–
Biliary tract	*E. coli*, *Klebsiella*, enterococci	*Clostridium* or *Bacteroides* (infrequent)
Small or large bowel	*E. coli*, *Klebsiella* spp., *Proteus* spp.	*Bacteroides fragilis* and other *Bacteroides*, *Clostridium*
Appendicitis	*E. coli*, *Pseudomonas*	*Bacteroides* spp.
Abscesses	*E. coli*, *Klebsiella*, enterococci	*B. fragilis* and other *Bacteroides*, *Clostridium*, anaerobic cocci
Liver	*E. coli*, *Klebsiella*, enterococci staphylococci, amoeba	*Bacteroides* (infrequent)
Spleen	*Staphylococcus*, *Streptococcus*	

Intraabdominal infection presents in many different ways and with a wide spectrum of severity. The regimen employed and duration of treatment depend on the specific clinical circumstances (i.e., the nature of the underlying disease process and the condition of the patient). Compromised patients require more aggressive therapies than do otherwise healthy patients who experience the same intraabdominal infection.

Recommendations 6 For most intraabdominal infections, the antimicrobial regimen should be effective against both aerobic and anaerobic bacteria.[28] When initial antimicrobial therapy is inappropriate, morbidity and mortality rates are higher than when appropriate agents are used.[29] Although it is impossible to provide antimicrobial activity against every possible pathogen, agents with activity against enteric gram-negative bacilli such as *E. coli* and *Klebsiella*, and anaerobes such as *B. fragilis* and *Clostridium* spp. should be administered. If most of the organisms can be eliminated through drainage or antimicrobials, the synergistic effect may be removed, and the patient's defenses may be able to resolve the remaining infection.

Table 123–6 presents the recommended agents for treatment of community-acquired and complicated intraabdominal infections from the Infectious Diseases Society of America and the Surgical Infection Society.[28,30,31] These recommendations were formulated using an evidence-based approach. Table 123–7 lists additional evidence-based recommendations. Most community-acquired infections are "mild to moderate," whereas healthcare-associated infections tend to be more severe, more difficult to treat, and more commonly resistant with bacteria or fungi. Table 123–8 presents guidelines for treatment and alternative regimens for specific situations. These are general guidelines; there are many factors that cannot be incorporated into such a table.

Most patients with severe intraabdominal infection, generalized peritonitis, or sepsis should be placed on a β-lactam–β-lactamase inhibitor combination or carbapenem such as imipenem, ertapenem, or meropenem. Combinations of an aminoglycoside with an antianaerobic agent, such as clindamycin or metronidazole, may be used, but such combinations are considered to be obsolete.[25] Gentamicin is the aminoglycoside of choice based on its lower cost. Other aminoglycosides, such as tobramycin or amikacin have no advantage in intraabdominal infection and generally are not drugs of first choice. Aztreonam may be used as an alternative to an aminoglycoside to avoid potential nephrotoxicity.

The dosage for aminoglycosides should be determined initially based on the patient's weight and renal function. Dosage adjustment should be performed by applying pharmacokinetic principles and by using peak and trough serum drug levels. Unless relatively resistant bacteria are suspected, a gentamicin or tobramycin peak concentration of 5 to 6 mcg/mL is usually effective. To achieve these serum concentrations, gentamicin or tobramycin dosage may range from 1 to 3 mg/kg per dose given as often as every 6 hours or as infrequently as every 48 hours if the patient has renal failure.

TABLE 123-6 Recommended Agents for the Treatment of Community-Acquired Complicated Intraabdominal Infections

Agents Recommended for Mild to Moderate Infections	Agents Recommended for High-Severity Infections
β-Lactamase inhibitor combinations	
Ampicillin-sulbactam[a]	Piperacillin-tazobactam
Ticarcillin-clavulanate	
Carbapenems	
Ertapenem	Imipenem/cilastatin
	Meropenem, doripenem
Combination regimens	
Cefazolin or cefuroxime plus metronidazole	Third- or fourth-generation cephalosporins (cefotaxime, ceftriaxone, ceftizoxime, ceftazidime, cefepime) plus metronidazole
Ciprofloxacin, levofloxacin, moxifloxacin, or gatifloxacin in combination with metronidazole	Ciprofloxacin in combination with metronidazole
	Aztreonam plus metronidazole

[a]Use of ampicillin-sulbactam may be associated with treatment failure due to increasing resistance of E. coli.

From Solomkin et al.,[28] and Mazuski et al.[30,32]

Because aminoglycosides have concentration-dependent killing and a relatively long postantibiotic effect for aerobic gram-negative bacilli, once-daily administration (5 to 7 mg/kg) is a reasonable alternative and appears to be equivalent to multiple daily dosing.

When used for intraabdominal infection, aminoglycosides should be combined with agents that are effective against the majority of *B. fragilis*. Clindamycin or metronidazole is the agent of first choice, but others, such as antianaerobic cephalosporins (e.g., cefoxitin, cefotetan, or ceftizoxime), piperacillin, mezlocillin, and combinations of extended-spectrum penicillins with β-lactamase inhibitors, would be suitable alternatives. Clindamycin should be administered intravenously in a dosage of 600 or 900 mg every 8 hours. Patients receiving multiple broad-spectrum antimicrobial agents who are immunocompromised should receive an oral antifungal agent (nystatin) for prevention of fungal overgrowth in the mouth and GI tract. The benefits of systemic antifungal prophylaxis (with fluconazole) have not been established for intraabdominal infection and should not be used routinely.

With intraabdominal contamination from the upper GI tract (perforation of a peptic ulcer or biliary tract disease), *B. fragilis* is an uncommon pathogen, and other agents therefore may be substituted for clindamycin or metronidazole. Alternatives include ampicillin, penicillin, or first-generation cephalosporins.

CLINICAL CONTROVERSY

Enterococci are often isolated from intraabdominal infections, and many antimicrobials are ineffective against enterococci (such as cephalosporins and fluoroquinolones). Regimens without activity against enterococci (gentamicin with clindamycin or cephalosporins) are generally effective in treating intraabdominal infections; however, there are numerous reports of enterococcal superinfection in immunocompromised patients, particularly after broad-spectrum antimicrobial use. The Infectious Disease Society of America guidelines state that "Routine coverage against enterococcus is not necessary for patients with community-acquired intraabdominal infections. Antimicrobial therapy for enterococci (e.g., ampicillin, penicillin, or vancomycin) should be given when enterococci are recovered from patients with "healthcare-associated infections."

TABLE 123-7 Evidence-Based Recommendations for Treatment of Complicated Intraabdominal Infections

	Grade of recommendation[a]
Acute contamination as a result of trauma	
Bowel injuries caused by penetrating, blunt, or iatrogenic trauma that are repaired within 12 hours and intraoperative contamination of the operative field by enteric contents under other circumstances should be treated with antibiotics ≤24 hours.	A-1
Acute appendicitis	
Acute appendicitis without evidence of gangrene, perforation, abscess, or peritonitis requires only prophylactic administration of inexpensive regimens active against facultative and obligate anaerobes.	A-1
Community-acquired infections	
Antibiotics used for empirical treatment of community-acquired intraabdominal infections should be active against empiric gram-negative aerobic and facultative bacilli and β-lactam–susceptible gram-positive cocci.	A-1
For patients with mild-to-moderate community-acquired infections, agents that have a narrower spectrum of activity, such as ampicillin-sulbactam, cefazolin, or cefuroxime-metronidazole, ticarcillin-clavulanate, and ertapenem are preferable to more costly agents that have broader coverage against gram-negative organisms and/or greater risk of toxicity.	A-1
Anaerobic coverage	
Coverage against obligate anaerobic bacilli should be provided for distal small-bowel and colon-derived infections and for more proximal gastrointestinal perforations when obstruction is present.	A-1
Nosocomial infections	
Agents used to treat nosocomial infections in the intensive care unit (e.g., expanded gram-negative bacterial spectrum) should not be routinely used to treat community-acquired infections.	B-2
If a patient with diagnosed infection has previously been treated with an antibiotic, that patient should be treated as if he or she has had a healthcare-associated (nosocomial) infection.	B-3
Aminoglycosides	
Aminoglycosides are not recommended for routine use in community-acquired intraabdominal infections.	A-1
Oral completion therapy	
Completion of the antimicrobial course with oral forms of a quinolone plus metronidazole,	A-1
or with amoxicillin-clavulanic acid is acceptable for patients who are able to tolerate an oral diet.	B-3
Suspected fungal infection	
Antiinfective therapy for *Candida* should be withheld until the infecting species is identified.	C-3
Enterococcal infection	
Routine coverage against *Enterococcus* is not necessary for patients with community-acquired intraabdominal infections.	A-1

[a]Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1 = Evidence from >1 properly randomized, controlled trial. 2 = Evidence from >1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies; from multiple time series, or from dramatic results from uncontrolled experiments. 3 = Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

From Solomkin et al.,[28] and Mazuski et al.[30,31]

Coverage for enterococci for most community-acquired intraabdominal infections is not recommended.[23] The failure of host defenses may be a critical factor in the pathogenicity of enterococci. In immunocompromised patients, patients with valvular

heart disease or a prosthetic heart valve, those who have had prior cephalosporin or carbapenem therapy, or those who have severe sepsis or septic shock, there is justification to provide specific antimicrobial activity against enterococci. In patients with healthcare-associated intraabdominal infections it is reasonable to include coverage of enterococcus in the initial regimen.[32] Ampicillin or other penicillins that are active against enterococci (e.g., penicillin, piperacillin, and mezlocillin) should be used in patients at high risk, patients with persistent or recurrent intraabdominal infection, or patients who are immunosuppressed, such as after organ transplantation. Ampicillin remains the drug of choice for this indication because it is most active in vitro against enterococcus and is relatively inexpensive. Vancomycin is active against most enterococci; however, resistance is increasing, and this agent should be reserved for established infections when first-line therapies cannot be used.

7 Intraperitoneal administration of antibiotics is preferred over IV therapy in the treatment of peritonitis that occurs in patients undergoing CAPD.[33] The International Society of Peritoneal Dialysis guidelines for the diagnosis and pharmacotherapy of peritoneal dialysis–associated infections provide dosing recommendations for intermittent and continuous therapy based on the modality of dialysis (CAPD or automated peritoneal dialysis) and the extent of the patient's residual renal function.[34] Third-generation cephalosporins, such as cefotaxime, remain the treatments of choice for primary peritonitis associated with cirrhosis.[35]

Antimicrobial agents effective against both gram-positive and gram-negative organisms should be used for initial intraperitoneal empiric therapy for peritonitis in peritoneal dialysis patients. The most important factors to take into consideration for initial antimicrobial selection are the dialysis center's and the patient's history of infecting organisms and their sensitivities. The use of cefazolin (loading dose [LD] 500 mg/L; maintenance dose [MD] 125 mg/L) plus ceftazidime (LD 500 mg/L; MD 125 mg/L) or cefepime (LD 500 mg/L; MD 125 mg/L) or an aminoglycoside (gentamicin-tobramycin LD 8 mg/L; MD 4 mg/L) is suitable for initial empiric therapy; if patients are allergic to cephalosporin antibiotics, vancomycin (LD 1,000 mg/L; MD 25 mg/L) or an aminoglycoside should be substituted. Another option is monotherapy with imipenem-cilastin (LD 500 mg/L; MD 200 mg/L) or cefepime. Antimicrobial doses should empirically be increased by 25% in patients with residual renal function (more than 100 mL/day urine output).[34] Antimicrobial therapy should be continued for at least 1 week after the dialysate fluid is clear and for a total of at least 14 days. The reader is referred to these guidelines for additional information.[34]

After acute bacterial contamination, such as with abdominal trauma where GI contents spill into the peritoneum, combination antimicrobial regimens are not required. If the patient is seen soon after injury (within 2 hours) and surgical measures are instituted promptly, antianaerobic cephalosporins (such as cefoxitin or cefotetan) or extended-spectrum penicillins are effective in preventing most infectious complications. Antimicrobials should be administered as soon as possible after injury.

For appendicitis, the antimicrobial regimen used should depend on the appearance of the appendix at the time of operation, which may be normal, inflamed, gangrenous, or perforated. Because the condition of the appendix is unknown preoperatively, it is advisable to begin antimicrobial agents before the appendectomy is performed. Reasonable regimens would be antianaerobic cephalosporins or, if the patient is seriously ill, a carbapenem or β-lactam–β-lactamase inhibitor combination. If, at operation, the appendix is normal or inflamed, postoperative antimicrobials are not required. If the appendix is gangrenous or perforated, a treatment course of 5 to 7 days with the agents listed in Table 123–8 is appropriate.

8 The necessary duration of treatment for intraabdominal infections is not clearly defined. Acute intraabdominal contamination, such as after a traumatic injury, may be treated with a very short course (24 hours).[36] For established infections (i.e., peritonitis or intraabdominal abscess), an antimicrobial course limited to 5 to 7 days is justified. This allows eradication of bacteria remaining in the peritoneum after a surgical procedure that may enter the peritoneum through healing suture lines. Under certain conditions, therapy for longer than 7 days would be justified (e.g., if the patient remains febrile or is in poor general condition, when relatively resistant bacteria are isolated, or when a focus of infection in the abdomen may still be present). For some abscesses, such as pyogenic liver abscess, antimicrobials may be required for a month or longer.

Intraperitoneal irrigation of antimicrobial agents for treatment of intraabdominal infection has been studied, often with conflicting results.[37] Intraoperative antimicrobial irrigation does not improve patient outcomes in comparison with copious intraoperative irrigation with normal saline. Possibly the most important aspect of peritoneal irrigation is the dilutional effect on bacteria and adjuvants that promotes infection (intestinal contents and hemoglobin). Most systemically administered antimicrobials easily cross the peritoneal membrane so that peritoneal fluid concentrations are similar to serum. Confined areas, such as an abscess, can be expected to attain much lower antimicrobial concentrations.

EVALUATION OF THERAPEUTIC OUTCOMES

Whichever antimicrobial regimen is chosen, the patient should be reassessed continually to determine the success or failure of therapies. The clinician should recognize that there are many reasons for poor patient outcome with intraabdominal infection; improper antimicrobial administration is only one. The patient may be immunocompromised, which decreases the likelihood of successful outcome with any regimen. It is impossible for antimicrobials to compensate for a nonfunctioning immune system. There may be surgical reasons for poor patient outcome. Failure to identify all intraabdominal foci of infection or leaks from a GI anastomosis may cause continued intraabdominal infection. Even when intraabdominal infection is controlled, accompanying organ system failure, most often renal or respiratory, may lead to patient demise. Finally, antimicrobial resistance may relate to treatment failure as isolates from intraabdominal infections are increasingly drug resistant.[38]

The outcome from intraabdominal infection is not determined solely by what transpires in the abdomen. Unsatisfactory outcomes in patients with intraabdominal infections may result from complications that arise in other organ systems. Infectious complications commonly associated with mortality after intraabdominal infection are urinary tract infections and pneumonia.[39] A high APACHE (Acute Physiology and Chronic Health Evaluation) II score, low serum albumin concentration, and high New York Heart Association cardiac function status were significantly and independently associated with increased mortality from intraabdominal infection.[40]

9 Once antimicrobials are initiated and the other important therapies described earlier are used, most patients should show improvement within 2 to 3 days. Usually, temperature will return to near normal, vital signs should stabilize, and the patient should not appear in distress, with the exception of recognized discomfort and pain from incisions, drains, and the nasogastric tube. At 24 to 48 hours, aerobic bacterial culture results should return. If a suspected pathogen is not sensitive to the antimicrobial agents being given, the regimen should be changed if the patient has not shown sufficient improvement. If the isolated pathogen is extremely sensitive to one antimicrobial and the patient is progressing well, concurrent antimicrobial therapy may often be discontinued.

TABLE 123-8 Guidelines for Initial Antimicrobial Agents for Intraabdominal Infections

	Primary Agents	Alternatives
Primary bacterial peritonitis		
Cirrhosis	Cefotaxime	1. Add clindamycin or metronidazole if anaerobes are suspected 2. Other third-generation cephalosporins, extended-spectrum penicillins, aztreonam, and imipenem as alternatives 3. Piperacillin–tazobactam
Peritoneal dialysis	Initial empiric regimens Cefazolin or cephalothin plus ceftazidime or cefepime	1. An aminoglycoside may be used in place of ceftazidime or cefepime 2. Imipenem/cilastatin or cefepime may be used alone 3. Quinolones may be used in place of ceftazidime or cefepime if local susceptibilities allow
	1. *Staphylococcus*: penicillinase-resistant penicillin or first-generation cephalosporin	1. Alternative for methicillin resistant staphylococci is vancomycin 2. For vancomycin-resistant *Staphylococcus aureus*, linezolid, daptomycin, or quinupristin-dalfopristin must be used
	2. *Streptococcus or Enterococcus:* ampicillin	1. An aminoglycoside may be added for enterococcal peritonitis 2. Linezolid or quinupristin-dalfopristin should be used to treat vancomycin-resistant enterococcus not susceptible to ampicillin
	3. Aerobic gram-negative bacilli: ceftazidime or cefepime 4. *Pseudomonas aeruginosa*: two agents with differing mechanisms of action, such as an oral quinolone plus ceftazidime, cefepime, tobramycin, or piperacillin	1. The regimen should be based on in vitro sensitivity tests
Secondary bacterial peritonitis		
Perforated peptic ulcer	First-generation cephalosporins	1. Antianaerobic cephalosporins[a] 2. Possibly add aminoglycoside if patient condition is poor 3. Aminoglycoside with clindamycin or metronidazole; add ampicillin if patient is immunocompromised or if biliary tract origin of infection
Other	Imipenem-cilastatin, meropenem, ertapenem, or extended-spectrum penicillins with β-lactamase inhibitor	1. Ciprofloxacin with metronidazole 2. Aztreonam with clindamycin or metronidazole 3. Antianaerobic cephalosporins[a]
Abscess		
General	Imipenem-cilastatin, meropenem, ertapenem, or extended-spectrum penicillins with β-lactamase inhibitor	1. Aztreonam with clindamycin or metronidazole 2. Ciprofloxacin with metronidazole 3. Aminoglycoside with clindamycin or metronidazole;
Liver	As above but add a first-generation cephalosporin	Use metronidazole if amoebic liver abscess is suspected
Spleen	Aminoglycoside plus penicillinase-resistant penicillin	Alternatives for penicillinase-resistant penicillin are first-generation cephalosporins or vancomycin
Appendicitis		
Normal or inflamed	Antianaerobic cephalosporins[a] (discontinued immediately postoperation)	1. Ampicillin-sulbactam
Gangrenous or perforated	Imipenem-cilastatin, meropenem, ertapenem, antianaerobic cephalosporins, or extended-spectrum penicillins with β-lactamase inhibitor	1. Aztreonam with clindamycin or metronidazole 2. Ciprofloxacin with metronidazole 3. Aminoglycoside with clindamycin or metronidazole
Acute cholecystitis	First-generation cephalosporin	Aminoglycoside plus ampicillin if severe infection
Cholangitis	Aminoglycoside with ampicillin with or without clindamycin or metronidazole	Use vancomycin instead of ampicillin if patient is allergic to penicillin
Acute contamination from abdominal trauma	Antianaerobic cephalosporins[a] or ampicillin-sulbactam	1. A carbapenem 2. Ciprofloxacin plus metronidazole
Pelvic inflammatory disease	Cefotetan or cefoxitin with doxycycline	1. Clindamycin with gentamicin 2. Ciprofloxacin with doxycycline and metronidazole

[a]Cefoxitin, cefotetan, and ceftizoxime.

CLINICAL CONTROVERSY

Although some investigators suggest that routine culturing of patients with community-acquired intraabdominal infections contributes little to their management,[33] other investigators suggest that antimicrobial therapy should be based on susceptibility of the bacteria collected from the operative site because this correlates with clinical outcome.[34]

With anaerobic culturing techniques and the slow growth of these organisms, anaerobes are often not identified until 4 to 7 days after culture, and sensitivity information is difficult to obtain. For this reason, there are usually few data with which to alter the antianaerobic component of the antimicrobial regimen. A report indicating that anaerobes were not isolated should not be the sole justification for discontinuing antianaerobic drugs because anaerobic bacteria that were present in the infectious process may not have been transported properly to the microbiology laboratory, or other problems may have led to cell death in vitro.

Reasons for antimicrobial failure may not always be apparent. Even when antimicrobial susceptibility tests indicate that an organism is susceptible in vitro to the antimicrobial agent, therapeutic failures may occur. Possibly there is poor penetration of the antimicrobial agent into the focus of infection, or bacterial resistance may develop after initiation of antimicrobial therapy. Also, it is possible that an antimicrobial regimen may encourage the development of infection by organisms not susceptible to the regimen being used. Superinfection in patients being treated for intraabdominal infection can be caused

by *Candida;* however, enterococci or opportunistic gram-negative bacilli such as *Pseudomonas* or *Serratia* may be involved.

Treatment regimens for intraabdominal infection can be judged as successful if the patient recovers from the infection without recurrent peritonitis or intraabdominal abscess and without the need for additional antimicrobials. A regimen can be considered unsuccessful if a significant adverse drug reaction occurs, reoperation or percutaneous drainage is necessary, or patient improvement is delayed beyond 1 or 2 weeks. The costs of treatment can be significantly reduced if parenteral antimicrobials can be switched to oral agents for completion of therapy.[41]

CHAPTER 124

Parasitic Diseases

J. V. ANANDAN

KEY CONCEPTS

1. All symptomatic adults and children older than 8 years of age with giardiasis can be treated with metronidazole 250 mg 3 times daily for 5 to 10 days, or tinidazole 2 g once, or nitazoxanide 500 mg twice daily for 3 days.
2. Amebic liver abscesses can spread to the lungs and pleura. Pericardial infections, although rare, may be associated with extension of the amebic abscess from the left lobe of the liver. Erosion of liver abscesses also present as peritonitis.
3. Asymptomatic cyst passers and patients with mild intestinal amebiasis should receive one of the following luminal agents: paromomycin 25 to 35 mg/kg/day 3 times daily for 7 days, iodoquinol 650 mg 3 times daily for 20 days, or diloxanide furoate 500 mg 3 times daily for 10 days.
4. Mebendazole (Vermox), an oral synthetic benzimidazole, is the agent of first choice for hookworm. It is also effective against ascariasis, enterobiasis, and trichuriasis.
5. Administration of corticosteroids or other immunosuppressive drugs to an infected individual with strongyloidiasis can result in hyperinfections and disseminated strongyloidiasis.
6. The most serious complication of cysticercosis is invasion of the central nervous system which results in neurocysticercosis. Neurocysticercosis can cause obstructive hydrocephalus, strokes, and seizures; antihelminthic treatment for these conditions remains controversial.
7. When intravenous quinidine is not readily available, intravenous artesunate (available under an investigational new drug (IND) from the CDC at *www.cdc.gov/malaria/features/artesunate_now_available.htm*), a water-soluble artemisinin derivative, administered at 2.4 mg/kg/dose for 3 days at 0, 12, 24, 48, and 72 hours is the recommended drug if severe *Plasmodium falciparum* is suspected.
8. Because *falciparum* malaria is associated with serious complications, including pulmonary edema, hypoglycemia, jaundice, renal failure, confusion, delirium, seizures, coma, and death, careful monitoring of fluid status and hemodynamic parameters is mandatory. Either hemofiltration or hemodiafiltration is indicated in renal failure.
9. The drugs that have been used to treat *Trypanosoma cruzi* infections include nifurtimox (Lampit, Bayer 2502) and benznidazole (Rochagan).
10. Permethrin (1% and 5%) for pediculosis and scabies, respectively, is the preferred agent and remains the safest agent, especially in infants and children.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Parasitic diseases continue to receive increasing attention from clinicians in the United States because of the high frequency of travel, deployment of personnel for humanitarian and military missions (e.g., Peace Corps volunteers), inflow of immigrants from a wider geographic distribution, and the presence of immunosuppressed populations (e.g., acquired immunodeficiency syndrome [AIDS] and transplant patients). Migrant farm workers who work and live in substandard hygienic conditions, the large and growing Central and South American immigrant population, and other inadequately screened immigrants from Asia represent significant sources of parasitic infections in the United States.[1–9] Clinicians need to have a heightened awareness of parasitic diseases and how to treat them. Clinical signs and symptoms, together with the patient's travel history, should be used with other diagnostic aids in the identification of parasitic diseases. Parasitic infections caused by pathogenic protozoa or helminths affect more than 3 billion people worldwide and impose tremendous health and economic burdens on developing countries.[9]

This chapter discusses the major parasitic diseases, including protozoan diseases (giardiasis, amebiasis, malaria, and Chagas disease), helminthic infections (ascariasis, enterobiasis, hookworm, strongyloidiasis, and cestodiasis), and ectoparasitic infestations (head and body lice). Emphasis is placed on diseases seen more frequently in the United States. World distribution of parasites depends on the presence of suitable hosts, habitats, and environmental conditions.[9] A human parasite that does not use an intermediate host is likely to be found in any inhabited region of the world as long as the environmental conditions are suitable. *Ascaris* (roundworm) and *Trichuris* (whipworm) require carelessness of habits for transfer and require time outside the human body, where they are exposed to heat and dryness, to reach the infective stage. The distribution of the hookworm is more limited because the free-living forms are unprotected by resistant shells or cysts. African trypanosomiasis never occurs outside the range of the tsetse fly; malaria normally never occurs beyond the range of the infective *Anopheles* mosquito; and schistosomiasis never occurs in the absence of a specific water snail. The prevalence of clonorchiasis (Chinese liver fluke) is an example of the impact of both environmental and geographic factors. Clonorchiasis requires the simultaneous presence of not only humans, specific snail species, and certain fish, but also unsanitary conditions that make the eggs accessible to the snails, an association of the snail and fish, and the established local habit of eating raw

fish. The ability of some parasites to infect hosts other than humans may perpetuate an infection even when human habits preclude the possibility of more than occasional access to the human body. In North America, the broad tapeworm (*Diphyllobothrium latum*) would perish if it were not that dogs and other carnivores, such as the brown bear, serve as reservoir hosts.

HOST–PARASITE RELATIONSHIP

Symbiosis is the association of two species for the purpose of obtaining food for either one or the other. *Parasitism* is a symbiotic relationship in which one species, the host, is injured through the activities of the other. Through evolution, parasites have made specific morphologic adaptations. Adaptation to the host has taken a number of forms: loss of locomotor organelles in the protozoan *Sporozoa*; partial and complete lack of digestive systems in the trematodes and cestodes, respectively; elaboration of proteolytic enzymes to penetrate the host intestinal mucosa by *Entamoeba histolytica*; the cercariae of the blood fluke that penetrate the skin of the host by elaborate enzymes; and, finally, the ability to infect an intermediate host to increase reproductive capacity, as seen among the cestodes and trematodes.[9]

Parasites normally inflict some degree of injury to the host, the extent of which depends on such factors as parasite load, nutritional status, and immunologic competence of the host. *Entamoeba coli* is considered commensal because it subsists on the bacterial flora of the gut and does not cause any harm to the host. Unlike *Entamoeba coli*, *Fasciolopsis buski*, the giant intestinal fluke, can produce severe local damage to the intestinal wall. *Ascaris*, the roundworm, can perforate the bowel wall, cause intestinal obstruction, and invade the appendix and bile duct. Malarial parasites destroy red blood cells by multiplying inside them. *Diphyllobothrium latum*, or the broad fish tapeworm, removes vitamin B_{12} from the gastrointestinal tract (GI) tract, resulting in megaloblastic anemia.[9]

PROTOZOAN DISEASES

GIARDIASIS

Epidemiology and Etiology

Giardia lamblia (also known as *Giardia intestinalis* or *Giardia duodenalis*), an enteric protozoan, is the most common intestinal parasite responsible for diarrheal syndromes throughout the world.[10–13] *Giardia* is the most frequently identified intestinal parasite in the United States, with a prevalence rate of 15% in some areas. *G lamblia* is the first enteric pathogen seen in children in developing countries, with prevalence rates between 15% and 30%.[12]

There are two stages in the life cycle of *G lamblia*: the trophozoite and the cyst. *G lamblia,* which is found in the small intestine, the gallbladder, and biliary drainage, is a pear-shaped trophozoite with four pairs of flagella. Two nuclei lie in the area of the sucking disk, giving the protozoan a characteristic face-like image.

The distribution of giardiasis is worldwide. Children seem to be affected more frequently than adults. Children in day care centers may infect parents and other family members.[12] In less developed countries, fecal contamination of the environment and lack of potable water, education, and housing continue to be risk factors for giardiasis among children.

Pathology

Giardiasis results from ingestion of *G lamblia* cysts in fecally contaminated water or food. The protozoan excysts under the stimulus of low gastric pH to release the trophozoite.[12] Colonization and multiplication of the trophozoite lead to mucosal invasion, localized edema, and flattening of the villi, resulting in malabsorption states in the host.[10–13]

Lactose intolerance precipitated by giardiasis can persist even after eradication of the protozoan. Achlorhydria, hypogammaglobulinemia, or deficiency in secretory immunoglobulin A (IgA) are predispositions for giardiasis.[10,12,13] Table 124–1 describes the clinical presentation of giardiasis.

TABLE 124-1 Clinical Presentation of Giardiasis

Acute onset
Diarrhea, cramp-like abdominal pain, bloating, and flatulence[10–12]
Malaise, anorexia, nausea, and belching[12]
Chronic
Diarrhea: foul-smelling, copious, light-colored, fatty stools; weight loss
Periods of diarrhea alternating with constipation
Steatorrhea, lactose intolerance, vitamin B_{12}, and fat-soluble vitamin deficiencies[10–14]

Diagnosis of giardiasis is made by examination of fresh stool or a preserved specimen during the acute diarrheal phase. Fresh stool specimens may show the trophozoites, whereas preserved specimens usually yield the cysts. If both the stool examination and string test prove unsuccessful, it may be necessary to attempt duodenal aspiration and biopsy to confirm the diagnosis; this may be more important in AIDS patients and in patients with hypogammaglobulinemia.[10,12] Most clinicians advocate a clinical trial of the standard therapy before undertaking invasive diagnostic tests. Detection of the trophozoites or cysts in fecal samples by enzyme-linked immunosorbent assay (ELISA) or immunofluorescence or identification of the *Giardia* antigen by counterimmunoelectrophoresis are alternative ways for diagnosis of giardiasis.[9,10,12,15]

TREATMENT

Giardiasis

DESIRED OUTCOME

To reduce morbidity and to avoid complications in patients identified with prolonged diarrhea and malabsorption and who have a recent history of travel to an endemic area, rapid identification by ova and parasite examination or by antigen detection test should be used to institute appropriate therapy.[13]

PHARMACOLOGIC THERAPY

1 All symptomatic adults and children older than 8 years of age with giardiasis can be treated with metronidazole 250 mg 3 times daily for 5 to 10 days, or tinidazole 2 g once, or nitazoxanide 500 mg twice daily for 3 days.[16] The alternative drugs include furazolidone 100 mg 4 times daily or paromomycin 25 to 35 mg/kg/day in divided doses daily for 1 week.[11–14,16,17] Paromomycin 25 to 35 mg/kg/day in three doses for 7 to 10 days is a safe agent in pregnancy.[10,12,16] The pediatric dose for metronidazole is 15 mg/kg/day 3 times daily for 5 to 7 days.[16] The pediatric dose of tinidazole is 50 mg/kg (maximum 2 g) once while nitazoxanide (Alinia) suspension is dosed at 100 mg every 12 hours (1–3 years), 200 mg every 12 hours (4–11 years) and the adult dose is recommended for children older than 12 years; all are administered for 3 days.[12,16] Quinacrine, which was the drug of choice in giardiasis, has been discontinued by the manufacturer but is obtained in the United States

from a specialized pharmacy (see Appendix 124–1). Albendazole 400 mg daily for 5 days has been cited to produce cure rates of 97% and as being equivalent to metronidazole in children. However, other investigators have disputed the efficacy of this agent.[17]

Evaluation of Therapeutic Outcomes

Patients with symptomatic giardiasis, positive stool samples, or the detection of *Giardia* antigen by counterimmunoelectrophoresis or ELISA should be treated with metronidazole for 5 to 7 days. Metronidazole produces cure rates of between 85% and 95%.[10,17] Diarrhea will stop within a few days, although in some patients it may take 1 to 2 weeks. Cyst excretion will cease within days; however, intestinal dysfunction (manifested as increased transit time) and radiologic changes (irregular thickening of the folds in the upper small intestine) may take a few months to resolve.[10] Patients who fail initial therapy with metronidazole should receive a second course of therapy. Nitazoxanide (500 mg twice daily for 3 days) is effective in patients who are not responding to metronidazole.[12] Pregnant patients can receive paromomycin 25 to 35 mg/kg/day in divided doses for 7 days. Metronidazole has been used in the second and third trimesters of pregnancy.[12] Giardiasis can be prevented by good personal hygiene and by caution in food and drink consumption.

AMEBIASIS

Epidemiology and Etiology

Because of its worldwide distribution and serious gastrointestinal manifestations, amebiasis is one of the most important parasitic diseases of humans.[9,18–21] The major causative organism in amebiasis is *E histolytica*, which inhabits the colon and must be differentiated from the *Entamoeba dispar* and a recently identified species, *E moshkovskii* which are associated with an asymptomatic carrier state. *E dispar* is considered nonpathogenic, while the status of *E moshkovskii* remains to be defined.[19] Although *E histolytica* and *E dispar* are indistinguishable morphologically, monoclonal antibodies have been used to separate the two.[20,21] The *Entamoeba histolytica* II kit (TechLab, Blacksburg, VA) remains the most specific test for *E histolytica*.[19] Invasive amebiasis is almost exclusively the result of *E histolytica* infection. Approximately 50 million cases of invasive disease result each year worldwide, leading to an excess of 100,000 deaths.[19,21] The incidence of amebiasis is estimated at approximately 4% in the general U.S. population.[21] The highest incidence is found in institutionalized mentally retarded patients, sexually active homosexuals, patients with AIDS, and new immigrants from endemic areas (e.g., Mexico, India, West and South Africa, and portions of Central and South America).[19,21]

Pathology

E histolytica invades mucosal cells of colonic epithelium, producing the classic flask-shaped ulcer in the submucosa.[19–23] The trophozoite has a cytolethal effect on cells through a toxin. If the trophozoite gets into the portal circulation, it will be carried to the liver, where it produces abscess and periportal fibrosis.[19–24] Amebic ulcerations can affect the colon, perineum, and genitalia, and abscesses may occur in the lung and brain.[20–24]

Clinical Presentation

The most frequent clinical manifestations of the disease are gastrointestinal (Table 124–2).

2 Amebic liver abscesses can spread to the lungs and pleura.[20,21] Pericardial infections, although rare, may be associated with extension of the amebic abscess from the left lobe of the liver. Erosion of liver abscesses also present as peritonitis.[19–22]

TABLE 124-2 Most Common Manifestations of Amebiasis

Intestinal disease
Vague abdominal discomfort, malaise to severe abdominal cramps, flatulence, bloody diarrhea (heme-positive in 100% of cases) with mucus[19–21]
Eosinophilia is usually absent, although moderate leukocytosis is not unusual[20,21]
Amebic liver abscess
High fever, rigors and profuse sweating, significant leukocytosis with left shift, elevated alkaline phosphatase, and liver tenderness on palpation[21,22,24]
Right-upper-quadrant pain, hepatomegaly, and liver tenderness, with referred pain to the left or right shoulder
Erosion of liver abscesses may also present as peritonitis[19–21]

Review of the patient's history and recent travel should be strongly emphasized. Intestinal amebiasis is diagnosed by demonstrating *E histolytica* cysts or trophozoites (may contain ingested erythrocytes) in fresh stool or from a specimen obtained by sigmoidoscopy. Three stool samples obtained 24 to 36 hours apart will produce a 60% to 90% yield for *E histolytica*. Microscopy may not differentiate between the pathogenic *E histolytica* and the nonpathogenic *E dispar* in stools. Sensitive techniques are available to detect *E histolytica* in stool, including ELISA and antigen detection.[19–21,23] Endoscopy with scraping or biopsy may provide more definitive diagnosis where stool examinations do not provide adequate evidence.[19,21]

When amebic liver abscess is suspected from initial physical examination and history, confirmatory diagnostic procedures will include serology and liver scans (using isotopes by ultrasound or computed tomography) or magnetic resonance imaging.[20,21] Leukocytosis (>10,000/mm^3) and an elevated alkaline phosphatase concentration (>75%) are common findings. In rare instances, needle aspiration of the hepatic abscess may be attempted using ultrasound guidance.[20–22,24]

TREATMENT

Amebiasis

DESIRED OUTCOME

In amebiasis, the goals of therapy are initially to eradicate the parasite by use of specific amebicides and then to render supportive therapy.

TREATMENT REGIMENS

A number of different regimens have been suggested depending on the category of amebiasis: asymptomatic cyst passers, intestinal amebiasis, and amebic liver abscess.[13,19–22] Electrolyte replacement, antibiotic therapy, and nutritional support are essential adjunctive treatment modalities. Large hepatic abscess or amebic pericarditis may require needle aspiration, percutaneous catheter drainage, or, rarely, surgery before drug therapy.[20–22] Most regimens require a combination of drugs administered concurrently or sequentially.[19,21,24]

A careful history should be taken when one of the differential diagnoses is ulcerative colitis because corticosteroid administration has the potential to unmask amebiasis and produce toxic megacolon.[22]

PHARMACOLOGIC THERAPY

Metronidazole (Flagyl), dehydroemetine, and chloroquine (Aralen) are tissue-acting agents, whereas iodoquinol (Yodoxin), diloxanide furoate (Furamide), and paromomycin (Humatin) are luminal

amebicides. A systemic agent may be so well absorbed that only small amounts of the drug stay in the bowel, which might prove ineffective as a luminal agent.[20–23] A luminal-acting agent, on the other hand, may be too poorly absorbed to be effective in the tissue. In the asymptomatic cyst passer, it is necessary to eradicate the causative agent from the lumen to prevent intestinal amebiasis or the development of amebic liver abscess. Drug effectiveness must be monitored by stool examination, that is, from one to three negative specimens from 1 to 3 months after treatment.

3 Asymptomatic cyst passers and patients with mild intestinal amebiasis should receive one of the following luminal agents: paromomycin 25 to 35 mg/kg/day 3 times daily for 7 days, iodoquinol 650 mg 3 times daily for 20 days, or diloxanide furoate 500 mg 3 times daily for 10 days.[16] These regimens have cure rates of between 84% and 96%.[21] Diloxanide furoate is available only from Ponorama Compounding Pharmacy (6744 Balboa Blvd., Van Nuys, CA 91406, (800) 247–9767; or Medical Center Pharmacy, New Haven, CT, (203) 688–6816].[16] The pediatric dose for paromomycin is the same as in adults, whereas the dose of iodoquinol is 30 to 40 mg/kg/day (maximum:2 g) in three doses for 20 days, and the dose of diloxanide furoate is 20 mg/kg/day in three doses for 10 days.[16] Paromomycin is the preferred luminal agent in pregnant patients.[13,21]

Patients with severe intestinal disease or liver abscess should receive metronidazole 750 mg 3 times daily for 10 days, followed by a course of one of the luminal agents indicated earlier.[13,20–21] Tinidazole 2 g mg once daily for 5 days has been suggested for amebic liver abscess.[16,22] In the pediatric patient, the dose of oral metronidazole is 50 mg/kg/day in divided doses to be followed by a luminal agent.[16] Patients who are too ill to take oral metronidazole should receive the drug in equivalent doses by the intravenous route.[21]

Evaluation of Therapeutic Outcomes

Followup in patients with amebiasis should include repeat stool examination, serology, colonoscopy (for colitis), or computed tomography (CT) (for liver abscess) between days 5 and 7, at the end of the course of therapy, and a month after the end of therapy. Most patients with either intestinal amebiasis or colitis will respond in 3 to 5 days with amelioration of symptoms. Patients with liver abscesses may take from 7 to 10 days to respond; patients not responding during this period may require aspiration of abscesses or exploratory laparotomy. Serial liver scans have demonstrated healing of liver abscesses over 4 to 8 months after adequate therapy.[22]

Sanitation and Preventive Measures

Travelers and tourists visiting an epidemic area should avoid local tap water, ice, salads, and unpeeled fruits. Water can be disinfected by the use of iodine (tincture of iodine or commercial sources: Potable Aqua tablet (Wisconsin Pharmacal) or 5% to 10% acetic acid, but boiled water is probably the safest. An alternative or additional measure may be to carry a portable water purifier (such as Safewater, Durango, CO, *www.outgear.com*). Because food handlers in Asia and Latin America may be a source of amebiasis, travelers should avoid eating at food stalls and open markets.

HELMINTHIC DISEASES

Most intestinal helminthic infections may not be associated with clearly defined manifestation of disease, but they can cause significant pathology.[9,25–33] One factor that determines the pathogenicity of helminths is their population density. Light infections may be fairly well tolerated, whereas high populations of intestinal helminths can result in predictable disease presentations. In the United States, these infections are seen most frequently in recent immigrants from Southeast Asia, the Caribbean, Mexico, and Central America.[1,8,26,27] Other populations that have a high risk of infestation include institutionalized patients (both young and elderly), preschool children in daycare centers, residents of Indian reservations, and homosexual individuals. Certain conditions and drugs (fever, corticosteroids, and anesthesia) can cause atypical localization of worms.[34–38] Immunocompromised hosts can be overwhelmed by some helminthic infections, such as strongyloidiasis.[34]

TABLE 124-3 Clinical Presentations of Nematode Infections and Cysticercosis

Hookworm[27]
Mild epigastric pain and tenderness, headache, fatigue, anemia, hypoproteinemia, and cutaneous larva migrans
Ascariasis[26]
Abdominal pain, right-upper-quadrant pain, biliary coli, cholangitis, pancreatitis, and abdominal obstruction
Enterobiasis[25]
Mild abdominal discomfort and perianal itch
Strongyloidiasis[35,37]
Gastrointestinal: abdominal pain, bloating, nausea, constipation, and small bowel obstruction
Cardiopulmonary: cough, wheezing, pleural effusion, chest pain, and dyspnea
Dermatologic/hematologic: pruritic linear streaks of lower thighs and buttocks and eosinophilia
Central nervous system: headache, altered mental status, and meningitis
Cysticercosis[41,42,45]
Abdominal pain, nausea, diarrhea, painless nodules on arms, chest, and legs, and myalgia
Neurocysticercosis: headache, intracranial hypertension, hydrocephalus, and seizures

NEMATODES

Hookworm Disease

This is an infection of the small intestine caused by either *Ancylostoma duodenale* or *Necator americanus*. *N americanus* is found in the southeastern United States, where the temperature and humidity provide the proper environment. *Ancylostoma* is seen rarely in the United States.[25,27]

The life cycles of both species of hookworm are similar. The adult worms live in the small intestine attached to the mucosa. The females liberate eggs, which are eliminated in the feces and develop into larvae. Infective larva enter the host in contaminated food or water or penetrate the skin, where a papular eruption with localized edema and erythema can result.

In the small intestine, where the adult worm lives attached to the mucosa, injury is usually caused by mechanical and lytic destruction of tissue. The loss of blood can lead to anemia and hypoproteinemia (Table 124–3).[26–29]

Stool should be examined for eggs and the rhabditiform larvae. Eosinophilia (30%–60%) may be present in patients during early infection.

TREATMENT

Hookworm Disease

4 Mebendazole (Vermox), an oral synthetic benzimidazole, is the agent of first choice in hookworm. It is also effective against ascariasis, enterobiasis, trichuriasis.[16,25,26] The adult dose for treatment of

hookworm infestation is 100 mg twice daily for 3 days. Pediatric patients older than 2 years of age should receive the same dose as adults.[13] Albendazole is an alternative agent.[13]

Ascariasis

Ascariasis is caused by the giant roundworm *Ascaris lumbricoides*. Female worms range from 20 to 35 cm in length. The worm is found worldwide but more commonly in areas where sanitation is poor. In the United States, endemic areas include southeastern parts of the Appalachian range and the Gulf Coast states.

Clinical Manifestations During migration of the larvae through the lungs, patients can present with pneumonitis, fever, cough, eosinophilia, and pulmonary infiltrates.[9,25,26] Other symptoms of ascariasis include abdominal discomfort, abdominal obstruction, vomiting, and appendicitis (see Table 124–3).[9,25,31,32] Diagnosis is made by demonstrating the characteristic egg in the stool.

TREATMENT

Ascariasis

In both adults and pediatric patients older than 2 years of age, the treatment for ascariasis is mebendazole (Vermox) 100 mg twice daily for 3 days.[16] An alternative drug for ascariasis is albendazole 400 mg as a single dose.[16]

Enterobiasis

Enterobiasis, or pinworm infection, is caused by *Enterobius vermicularis*. The pinworm is a small, thread-like, spindle-shaped worm about 1 cm in length. It is the most widely distributed helminthic infection in the world. There are estimated to be 42 million cases in the United States.[25] The majority of those infected are children.

The most common problem with enterobiasis is cutaneous irritation in the perianal region, made by the migrating females or the presence of eggs. However, there are reports of other complications, including appendicitis and intestinal perforation.[33] The intense pruritus and scratching can cause dermatitis and secondary bacterial infections. In children, the itching can cause loss of sleep and restlessness (see Table 124–3).

The most effective method of diagnosing pinworm infections is by the use of perianal swab using adhesive Scotch tape. The Scotch tape, which is applied to the perianal region with a tongue depressor, is examined microscopically for eggs.[9,25]

TREATMENT

Enterobiasis

The common agents for treatment include pyrantel pamoate, mebendazole, or albendazole (Albenza). The dose of pyrantel pamoate is 11 mg/kg (maximum 1 g) as a single dose that can be repeated in 2 weeks. The dose of mebendazole for adults and children older than 2 years of age is 100 mg as a single dose; this may be repeated in 2 weeks.[16,25] The dose of albendazole for adults and children older than 2 years of age is 400 mg, and should be repeated in 2 weeks.[25] Following treatment, all bedding and underclothes should be sterilized by steaming or washing in the hot water cycle of a regular washing machine; this will eradicate the eggs. Bathroom rugs and toilet accessories also should be cleaned in a similar way.

Strongyloidiasis

Strongyloidiasis is caused by *Strongyloides stercoralis*, which has a worldwide distribution and is predominantly prevalent in South America (Brazil and Columbia) and in Southeast Asia. Strongyloidiasis is primarily seen among institutionalized populations (mental homes, mentally disabled children's homes) and immunocompromised individuals (patients with human immunodeficiency virus [HIV], AIDS, and hematologic malignancies).[8,34–38] The worm is usually found in the upper intestine where the eggs are deposited and hatch to form the rhabditiform larvae. The rhabditiform larvae (male and female) migrate to the bowel where they may be excreted in the feces. If excreted in the feces, the larvae can evolve into either one of two forms after copulation: (a) free-living noninfectious rhabditiform larvae or (b) infectious filariform larvae. The filariform larvae can penetrate host skin, travel to the lungs via the bronchi and glottis and make their way to the small intestine. At times, the filariform larvae may not pass out in the feces but instead migrate to the lungs and produce progeny, a process called autoinfection. This can result in hyperinfection (i.e., increased number of larvae in intestine, lungs, and other internal organs), especially in immunocompromised hosts.[34–36]

Symptoms with acute infection may appear with localized pruritic rash but heavy infestations can produce eosinophilia (10%–15%), diarrhea, abdominal pain, and intestinal obstruction (see Table 124–3).[37–39]

5 Administration of corticosteroids or other immunosuppressive drugs to an infected individual can result in hyperinfections and disseminated strongyloidiasis.[34,36,38] Diagnosis of strongyloidiasis is made by identification of the rhabditiform larvae in stool, sputum, duodenal fluid, and cerebrospinal fluid, by small bowel biopsy specimens, or by antigen testing (ELISA assay).[37]

TREATMENT

Strongyloidiasis

The drug of choice for strongyloidiasis is oral ivermectin 200 mcg/kg/day for 2 days and the alternative is albendazole 400 mg twice daily for 7 days.[16,34,39,40] In a patient with hyperinfection or disseminated strongyloidiasis, immunosuppressive drugs should be discontinued and treatment initiated with ivermectin 200 mcg/kg/day until all symptoms are resolved (duration, 5 to 14 days). Patients should be tested periodically to ensure the elimination of the larvae.[39] Individuals from endemic areas, who are candidates for organ transplantation, must be screened for *S stercoralis*.

Taenia solium: Cysticercosis and Neurocysticercosis

Tapeworm infection caused by *Taenia solium* is a result of ingestion of poorly cooked pork that contains the larvae or cysticercus.[41,42] Cysticercus, when released from the contaminated meat by host digestive juices, matures into the adult tapeworm and attaches to the host jejunum. Cysticercosis is a systemic disease caused by the larva of *T solium* (oncosphere) and is usually acquired by ingestion of eggs in contaminated food or by autoinfection.[41–43] The larvae can penetrate the bowel and migrate through the bloodstream to infect different organs including the central nervous system (neurocysticercosis).[43,44,46] The larvae matures in about 8 weeks and remain as a semitransparent, oval-shaped, fluid-filled bladder in tissues. In the United States, the highest incidence of cysticercosis has been reported in immigrants from Mexico.[41–43] Cysticercosis in most tissues may not produce major symptoms

and usually manifest as subcutaneous nodules, primarily in the arms, legs, and chest. However, penetration of the larval stage (cysticercus) into the central nervous system can produce hydrocephalus, intracranial hypertension, stroke, and seizure activity.[42] Epileptic seizures (50% to 80%) may be the presenting symptoms in patients with neurocysticercosis (see Table 124–3).[42,45] Clinical presentation, primarily seizure history, together with radiographic demonstration (CT and magnetic resonance imaging) of the cysticercus within the bladder or calcified cysts in the central nervous system, is diagnostic for neurocysticercosis.[41,42] Serologic diagnosis is made by the use of an enzyme-linked immunoelectrotransfer blot assay, which is considered highly sensitive and specific for cysticercosis.[41,42,45,46]

CLINICAL CONTROVERSY

4 Cysticercosis (excluding neurocysticercosis) is normally not treated. The management for neurocysticercosis remains controversial but may include surgery, anticonvulsants (neurocysticercosis-induced seizures), and antihelminthic therapy.[41,42,45,47] Antihelminthic therapy, if one decides this is an option, is albendazole 400 mg twice daily for 8 to 30 days.[16] However, the dose and duration of therapy with albendazole is not clearly defined.[42,47] The pediatric dose of albendazole is 15 mg/kg (maximum 800 mg) in two divided doses for 8 to 30 days. The doses for both adults and pediatric subjects may be repeated if necessary. Praziquantel is an alternative therapy.[16]

TREATMENT

Helminthic Diseases

Evaluation of Therapeutic Outcome

Morbidity and disease with intestinal nematodes are related to the intensity of infection or worm burden; subjects with transient exposure have less severe disease. The major adverse effects of intestinal nematodes are malnutrition, fatigue, and diminished work capacity. Treatment with antihelminthic agents results in complete eradication and significant change in the well-being of patients. Unlike other nematode infections, strongyloidiasis can perpetuate itself by autoinfection, and in the immunosuppressed host, the filariform larvae can invade various organs (e.g., lungs, central nervous system, and the like) to produce disseminated infection that can be fatal.[9,43–47]

6 The most serious complication of cysticercosis is invasion of the central nervous system which results in neurocysticercosis. Neurocysticercosis can cause obstructive hydrocephalus, strokes and seizures; antihelminthic treatment for these conditions remains controversial.[42,45,46]

MALARIA

Malaria represents the most devastating disease in terms of human suffering and economics. It affects the largest number of people (between 300 and 500 million new infections are reported annually) in the world, and between 1 to 2 million deaths worldwide.[3,5,48–50] In the United States, deaths from malaria are preventable. The primary reasons for deaths are failure to take chemoprophylaxis, inappropriate chemoprophylaxis, delay in seeking medical care, and misdiagnosis.[3,4,7,50]

EPIDEMIOLOGY

The exact geographic distribution of the various species is not well documented; it is reported that *Plasmodium vivax* is more prevalent in India, Pakistan, Bangladesh, Sri Lanka, and Central America; whereas *P falciparum* is predominant in Africa, Haiti, Dominican Republic, the Amazon region of South America, and New Guinea. Most of the infections with *Plasmodium ovale* occur in Africa, and the distribution of *Plasmodium malariae* is considered worldwide.[7,49,60]

In the United States, most cases of malaria are reported in immigrants from endemic areas and in American travelers. Blood transfusion also has been cited as a cause of malarial infection.[48,51]

ETIOLOGY

Malaria is transmitted by the bite of an infected *Anopheles* mosquito that introduces the sporozoites (tissue parasites) of the plasmodia (*P falciparum*, *P vivax*, *P malariae*, and *P ovale*) into the bloodstream. The asexual reproduction stage develops in humans, whereas the sexual stage occurs in the mosquito.[9,48,49] The sporozoites invade parenchymal hepatocytes, multiply in stages referred to as *exoerythrocytic stages*, and become hepatic vegetative forms or schizonts. Schizonts rupture to release daughter cells, or merozoites, that then infect erythrocytes.

P falciparum and *P malariae* remain in the primary exoerythrocytic stage in the liver for about 4 weeks before invading erythrocytes, whereas *P vivax* and *P ovale* can exist in the liver in the latent exoerythrocytic form for extended periods, and, therefore, infected subjects can experience relapses. The merozoites that invade the erythrocytes develop sequentially into ring forms, trophozoites, schizonts, and finally, merozoites, which can invade other erythrocytes or can develop into gametocytes, which undergo the sexual stage in the *Anopheles* vector. Because erythrocytic forms never reinvade the liver without developing into sporozoites in the vector, malaria infections from transfusion never result in the exoerythrocytic, or "liver," form.[9,49] *P falciparum* can result in high levels of parasitemia because of its ability to invade erythrocytes of all ages, unlike *P vivax* and *P ovale*, which only invade young cells.[48,49]

PATHOLOGY

The erythrocytic phase causes extensive hemolysis, which results in anemia and splenomegaly. The most serious complications usually are associated with *P falciparum* infections.[48–50,52–60] Infants and children younger than 5 years of age and nonimmune pregnant women are at high risk for severe complications from falciparum malaria.[52–55] The complications associated with falciparum malaria are primarily a result of the high parasitemia and the ability of the parasites to sequester in capillaries and postcapillary vessels of organs such as the brain and the kidney. It has been postulated that tissue hypoxia from anemia, together with *P falciparum*–parasitized red blood cell adherence to endothelial cells in capillaries, contribute to extensive vascular disease and severe metabolic effects.[52,53] *P malariae* is implicated in immune-mediated glomerulonephritis and nephrotic syndrome (Table 124–4).[49,52]

To ensure a positive diagnosis, blood smears should be obtained every 12 to 24 hours for 3 consecutive days.[9,49,52] The presence of parasites in the blood 3 to 5 days after initiation of therapy suggests drug resistance. Recent advances for detecting malaria parasite

TABLE 124-4 Clinical Presentation of Malaria

Initial presentation
Nonspecific fever, chills, rigors, diaphoresis, malaise, vomiting[48,49,52]
Orthostatic hypotension
Electrolyte abnormalities
Erythrocytic phase
Prodrome: headache, anorexia, malaise, fatigue, myalgia
Nonspecific complaints such as abdominal pain, diarrhea, chest pain, and arthralgia
Paroxysm: high fever, chills, and rigor[9,49,52,59]
Cold phase: severe pallor and cyanosis of the lips[9,49,52]
Hot phase: fever between 40.5°C (104.9°F) and 41°C (105.8°F)
Sweating phase:
Follows hot phase by 2–6 hours
Fever resolves
Marked fatigue and drowsiness, warm, dry skin, tachycardia, cough, severe headache, nausea, vomiting, abdominal pain, diarrhea, and delirium
Lactic acidosis and hypoglycemia (with falciparum malaria)[48,49,52,59]
Anemia
Splenomegaly
***P falciparum* infections**
Hypoglycemia, acute renal failure, pulmonary edema, severe anemia, thrombocytopenia, high-output heart failure, cerebral congestion, seizures and coma, and adult respiratory syndrome[49,52,59]

have included DNA or RNA probes by polymerase chain reaction (PCR) and rapid dipstick tests (*Para* Sight F, Becton-Dickinson, Cockeysville, MD) and OptiMAL.[48,49,52] The dipstick is reported to have a sensitivity of 88% and a specificity of 97%; however, microscopy is still considered the optimal test.

TREATMENT

Malaria

DESIRED OUTCOME

The primary goal in the management of malaria is the rapid diagnosis of the *Plasmodia* spp by blood smears (repeated every 12 hours for 3 days) so as to initiate timely antimalarial therapy to eradicate the infection within 48 to 72 hours and to avoid complications such as hypoglycemia, pulmonary edema, and renal failure that are responsible for increased mortality in malaria.[49]

PHARMACOLOGIC THERAPY

In adults (including pregnant women), the chemoprophylaxis for all species of *Plasmodium* is chloroquine phosphate 300 mg (base) once weekly beginning 1 to 2 weeks prior to departure and continued for 4 weeks after leaving an endemic area.[16,48,49,52,61–63] The pediatric dose of chloroquine phosphate is 5 mg (base) per kilogram of body weight (maximum 300 mg). When departing an area endemic for *P vivax* or *P ovale*, primaquine phosphate 30 mg (base) daily for 14 days beginning the last 2 weeks of chloroquine prophylaxis should be added to the regimen. The pediatric dose of primaquine is 0.6 mg (base) per kilogram of body weight per day for 14 days. The pediatric doses of chloroquine can be calculated based on body weight, and the tablets can be pulverized and placed in gelatin capsules. Parents can be instructed to suspend the dose in food, simple syrup, chocolate milk, or in a drink.[61]

In areas where chloroquine-resistant *P falciparum* strains exist, travelers should receive mefloquine (Lariam) for prophylaxis. The adult dose of mefloquine is 250 mg once weekly beginning 1 week prior to departure and continuing for the full period of exposure, followed by 250 mg for 4 weeks after last exposure.[16,48,49] The pediatric dose of mefloquine for prophylaxis is based on body weight.[16]

Body Weight (kg)	Dose
5 to 10 kg	one-eighth tablet/week
11 to 20 kg	one-quarter tablet/week
21 to 30 kg	one-half tablet/week
31 to 45 kg	three-quarters tablet/week
>45 kg	1 tablet/week

For travelers who are at immediate risk for drug-resistant *falciparum* malaria, a loading dose of mefloquine may be considered (except for travel to Thailand, Myanmar, Vietnam, Laos, and Cambodia, where atovaquone-proguanil combination, one tablet daily 2 days prior to departure and through the stay and 1 week after leaving area, may be an alternative).[49] Mefloquine is administered at 250 mg daily for 3 days before travel, followed by 250 mg once weekly while in the endemic area and continued for 4 weeks after last exposure.[48,49] Patients may experience neuropsychiatric reactions from mefloquine and may need to be monitored closely.[16,62–64]

An alternative regimen for prophylaxis in chloroquine-resistant areas for those who cannot tolerate mefloquine or Malarone, is to take oral doxycycline 100 mg daily starting 1 to 2 days prior to departure, during the exposure period, and continuing for 4 weeks after leaving the endemic area.[16] Children older than 8 years of age should receive 2 mg/kg/day (up to 100 mg) of doxycycline. Doxycycline is contraindicated in children younger than 8 years of age, in pregnant women, and during breastfeeding.[16,49,63,65]

In an uncomplicated attack of malaria (for all plasmodia except chloroquine-resistant *P falciparum*), the recommended regimen is chloroquine 600 mg (base) initially, followed by 300 mg (base) 6 hours later, and then 300 mg (base) daily for 2 days. In severe illness or when oral therapy is not tolerated or parenteral quinine is not available, quinidine gluconate 10 mg/kg as a loading dose (maximum 600 mg) in 250 mL normal saline should be administered slowly over 1 to 2 hours, followed by continuous infusion of 0.02 mg/kg/minute until oral therapy can be started.[16,48,49] In patients who have received either quinine or mefloquine, the loading dose of quinidine should be omitted. Oral quinine (650 mg every 8 hours) together with doxycycline 100 mg twice daily should follow the intravenous dose of quinidine to complete a total of 7 days of therapy.[16,48,60] The pediatric dose of intravenous quinidine gluconate is the same as the dose for adults.[16] The pediatric dose of quinine is 30 mg/kg/day in three divided doses for 7 days. Children younger than age 8 years and pregnant women should get clindamycin 20 mg/kg/day in divided doses for 7 days instead of doxycycline.[16,49,60]

7 When intravenous quinidine is not readily available, intravenous artesunate (available under an IND from the CDC at *www.cdc.gov/malaria/features/artesunate_now_available.htm*), a water-soluble artemisinin derivative, administered at 2.4 mg/kg/dose for 3 days at 0, 12, 24, 48, and 72 hours is the recommended drug if severe *P falciparum* is suspected.[16,58]

In *P falciparum* (chloroquine-resistant) infections, a dose of 750 mg mefloquine followed by 500 mg 12 hours later is recommended. The pediatric dose of mefloquine is 15 mg/kg (<45 kg body weight) followed by 10 mg/kg 8 to 12 hours later.[16] Intravenous quinidine gluconate (or intravenous artesunate) followed by oral quinine plus doxycycline to complete a total of 7 days of therapy should follow in a severe illness, as already indicated.[16,49] An alternative oral treatment for chloroquine-resistant *P falciparum* infection in adults, especially in those with a history of seizures or psychiatric disorders, is the combination of

atovaquone 250 mg and proguanil 100 mg (Malarone) (4 tablets daily for 3 days).[16,48,49] An alternative to Malarone is the combination product of artemether 20 mg and lumefantrine 120 mg (Coartem) recently approved by the FDA in the United States (for regimen, see *http://www.cdc.gov/malaria/pdf/treatmenttable.pdf*). The intravenous quinidine regimen requires close monitoring of the electrocardiogram and other vital signs (e.g., hypotension, QT interval prolongation, and hypoglycemia).[16,49,55,60]

8 Because *falciparum* malaria is associated with serious complications, including pulmonary edema, hypoglycemia, jaundice, renal failure, confusion, delirium, seizures, coma, and death, careful monitoring of fluid status and hemodynamic parameters is mandatory.[48,49,55,60] Either hemofiltration or hemodiafiltration is indicated in renal failure.[55]

Malarial infection does not produce immunity in patients, and active research has been initiated to develop a malaria vaccine.[66–68] A vaccine that blocks the entry of sporozoites into the liver cells will prevent malaria at this stage. However, immunity to sporozoites does not protect the host against parasites in the erythrocytic cycle. Infective sporozoites of *P falciparum* are covered by a polypeptide, circumsporozoite protein. Isolation and identification of the gene encoding for this circumsporozoite protein have led to the development of a monoclonal antibody by recombinant DNA technology; *P falciparum* sporozoite vaccine is now under investigation.[68]

CLINICAL CONTROVERSY

Because there remains public concern with mefloquine therapy, primarily about its neuropsychiatric effects,[16,63] an alternative regimen for chemoprophylaxis is the combination of atovaquone and proguanil (Malarone): 1 tablet daily beginning 1 to 2 days prior to travel and continuing for the duration of stay and 1 week after leaving the area.[16,62] Daily primaquine 30 mg (base) also has been recommended for prophylaxis for both *P vivax* and *P falciparum* malaria.[16]

EVALUATION OF THERAPEUTIC OUTCOMES

When advising potential travelers on prophylaxis for malaria, be aware of the incidence of chloroquine-resistant *P falciparum* malaria and the countries where this is prevalent.[16,62,63] Detailed recommendations for prevention of malaria may be obtained by checking the websites *www.cdc.gov/travel/* or *www2.cdc.gov/mmwr/*[63,69] or calling the U.S. Centers for Disease Control and Prevention (CDC) (see Appendix 124–1). In view of the increasing incidence of *P falciparum* resistance to antimalarials, newer drugs are under active study and include the water-soluble artesunate and the oil-soluble artemether and combinations with other agents.[7,16,49,63,70–75]

Acute *P falciparum* malaria resistant to chloroquine should be treated with intravenous quinidine or artesunate.[16,58] Patients receiving intravenous quinidine should have a central venous catheter to follow fluid status, and the electrocardiogram should be monitored closely. Hypoglycemia that is associated with *P falciparum* should be checked and corrected with dextrose infusions.[48,49,55] Quinidine infusion should be slowed temporarily or stopped if electrocardiogram shows a QT interval of greater than 0.6 seconds, an increase in the QRS complex to greater than 50%, or hypotension unresponsive to fluid challenge results. The suggested quinidine levels should be maintained at 3 to 7 mg/L.[49] Blood smears should be checked every 12 hours until parasitemia is less than 1%. Resolution of fever should take place between 36 and 48 hours after initiation of the intravenous quinidine therapy and the blood should be clear of parasites in 5 days.[48,49,52] If parenteral therapy is required for more than 48 hours, the dose of quinidine should be lowered by half.[16]

Travelers to endemic areas for malaria should be advised to remain in well-screened areas, to wear clothes that cover most of the body, and to sleep in mosquito nets.[4,7,49,71] It is prudent to carry the insect repellent DEET (N,N,diethyl-metatol) or Picaridin (Cutter Advanced) insect spray for use in mosquito-infested areas. Readers are urged to check publications from the CDC for the list of countries where chloroquine-resistant *P falciparum* exist.[16,69]

AMERICAN TRYPANOSOMIASIS

ETIOLOGY

Two distinct forms of the genus *Trypanosoma* occur in humans. One is associated with African trypanosomiasis (sleeping sickness) and the other with American trypanosomiasis (Chagas disease).[76–79] *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense* are the causative organisms for the East African and West African trypanosomiasis, respectively. *T brucei rhodesiense* causes the acute disease and is the more virulent of the two species. Both East and West African trypanosomiasis are transmitted by various species of tsetse fly belonging to the genus *Glossina*. Further discussion of this subject will focus on American trypanosomiasis.

Trypanosoma cruzi is the agent that causes American trypanosomiasis. American trypanosomiasis is transmitted by a number of species of a reduviid bug (*Triatoma infestans*, *Rhodnius prolixus*) that live in wall cracks of houses in rural areas of North, Central, and South America. The reduviid bug is infected by sucking blood from animals (e.g., opossums, dogs, and cats) or humans infected with circulating trypomastigotes (Table 124–5).

In chronic trypanosomiasis, patients present with cardiomyopathy and heart failure. Electrocardiograms are usually abnormal, demonstrating extrasystoles, first-degree heart block, right bundle-branch block, and other serious conduction disturbances.[77–79] Degeneration of the autonomic ganglia in the smooth muscle of the esophagus and colon leads to uncoordinated peristalsis. The end result has been reported to be "megasyndromes" of affected organs.[78–79] Penetration of the central nervous system results in meningoencephalitis, strokes, seizures, and focal paralysis.[78–80]

A history to verify the possible exposure to *T cruzi* should be an important initial diagnostic workup. Recovery of *T cruzi* is definitive, but this is not always possible, especially in chronic disease. Positive serologic tests using indirect immunofluorescent antibody test and ELISA (Chagas' EIA, Abbott Laboratories, Abbott Park, IL) may be diagnostic for the disease. The only serologic test available in the United States is Chagas' Kit (Hemagen Diagnostics, Inc., Columbia, MD).[78] A PCR test has also been used for diagnosis of *T cruzi*.[81] Specimens may be sent to the CDC for testing. All candidates from an endemic area for Chagas disease who are candidates for transplantation should be tested for *T cruzi*.[82]

TABLE 124-5 Clinical Presentation of South American Trypanosomiasis

Acute
Unilateral orbital edema ("Romana sign")[78,79]
Granuloma or "chagoma"
Fever, hepatosplenomegaly, and lymphadenopathy
Chronic
Cardiac: cardiomyopathy and heart failure
ECG: first-degree heart block, right bundle-branch block, and arrhythmias[76–78]
Gastrointestinal: enlargement of esophagus and colon ("mega" syndrome)[76,78]
Central nervous system: meningoencephalitis, strokes, seizures, and focal paralysis[78–80]

TREATMENT

American Trypanosomiasis

DESIRED OUTCOME

The primary goal of drug therapy in trypanosomiasis is to reduce the duration and severity of the illness and to decrease mortality.

PHARMACOLOGIC THERAPY

9 The drugs that have been used to treat *T cruzi* infections include nifurtimox (Lampit, Bayer 2502) and benznidazole (Rochagan).[16,78,79,83] Oral nifurtimox is available from the CDC, whereas benznidazole is only available in Brazil. Neither of these agents are optimal therapy and there is ongoing search for newer agents.[76,78] The adult dose of nifurtimox is 8 to 10 mg/kg/day in divided doses for 120 days. Because pediatric patients tolerate the drug better than adults, the dose for children age 1 to 10 years is 15 to 20 mg/kg/day, and for children age 11 to 16 years it is 12.5 to 15 mg/kg/day in divided doses.[16] Symptomatic treatment for heart failure includes digitalis and diuretics; the gastrointestinal complications, however, may require surgical revisions and reconstruction.[78,79]

EVALUATION OF THERAPEUTIC OUTCOMES

American trypanosomiasis (Chagas disease), which is endemic in all Latin American countries, can be transmitted congenitally, by blood transfusion, and by organ transplantation.[78,79] Treatment with nifurtimox of the acute phase (i.e., fever, malaise, edema of face, generalized lymphadenopathy, and hepatosplenomegaly) produces between 10% and 30% cure rates.[78] Treatment of chronic infection with nifurtimox is not recommended. It is essential to identify *T cruzi*–infected patients by serology and to monitor the cardiovascular status of these patients by electrocardiogram periodically. The congestive failure of cardiomyopathic Chagas disease is treated the same way as cardiomyopathies from other causes.[76,78]

ECTOPARASITES

A parasite that lives on the outside of the body of the host is called an *ectoparasite*. Approximately 6 to 12 million people become infested with pediculosis yearly in the United States.[84] Pediculosis usually is associated with poor personal hygiene, and infections are passed from person to person through social and sexual contact. The three types of human lice belong to two genera: *Pediculus*, including the head and body lice, and *Phthirus*, with only one species, the crab louse.[9,84,85] The human louse is detectable to the human naked eye and measures approximately 2 to 3 mm in length.

LICE

The two species that belong to this group include *Pediculus humanus capitis* (head louse) and *Pediculus humanus corporis* (body louse). Female lice deposit eggs on the hair. The eggs (or nits) remain firmly attached to the hair, and in about 10 days, the lice hatch to form nymphs, which mature in 2 weeks. Using both their piercing mouth parts and a pumping device, the larva and adults feed on the blood of the host. The body louse and head louse are essentially identical, although they live on different parts of the body. Unlike the head louse, which lives on the hair, the body louse is more frequently found on clothing of the infected host.

Pubic or crab lice are found on the hairs around the genitals, although they can occur in other areas of the body (e.g., eyelashes, beards, and axillae). Patients usually complain of severe pruritus from papular lesions produced by the bite of the louse. Hypersensitivity to foreign material injected by the lice can produce macular swellings and occasionally can lead to secondary bacterial infections.[84]

TREATMENT

Lice

The goal of therapy is to eradicate the causative organisms and provide symptomatic relief to patients. The agent of choice for all three infections (body, head, and crab lice) is 1% permethrin (Nix).[84–88] Permethrin is a derivative of the flowers of the plant *Chrysanthemum cinerariifolium*. The term *pyrethrin* is usually applied to several esters of chrysanthemic acid and pyrethric acid. Permethrin has both pediculicidal and ovicidal activity against *P humanus* var *capitis*. The cure rate is reported to be in the range of 85% to 95%.[84] Individuals who have a history of ragweed or chrysanthemum allergy should use this compound with caution. The side effects reported with permethrin products include itching, burning, stinging, and tingling. Permethrin 1% is applied to the scalp after the hair has been dried following a shampooing. The scalp should be saturated with permethrin liquid, and a towel should be wrapped around the scalp to allow the application to stay on for 10 minutes. The hair then should be rinsed thoroughly. A cream rinse of permethrin 1% (Nix-Creme Rinse) is also available. To ensure complete eradication, especially of newly hatched lice, it may be necessary to repeat the application. Recently the FDA-approved benzyl alcohol 5% (Ulesfia; Sciele Pharma Inc, Atlanta, GA) as an alternative therapy for head lice.[86]

There is increasing lice resistance to permethrin 1%.[85,88,89] An alternative preparation for lice is 0.5% malathion (Ovide), which is very effective.[16,87] To ensure complete eradication of lice infestation, the malathion application should be left on the scalp for about 90 minutes.[87] For the relief of pruritus, a soothing lotion of calamine liniment or lotion with 0.1% menthol may be used. Other members of the family or sexual partners also should be treated. All bedding and clothes should be sterilized by boiling or washing in the hot water cycle of the washing machine to avoid reinfections. Seams of clothes should be examined to verify that all organisms are eradicated. An ocular lubricant (e.g., Lacri-Lube S.O.P.) applied twice daily may be used to remove crab louse infection of the eyelids.

SCABIES

Scabies is caused by the itch mite *Sarcoptes scabiei*, which affects both humans and animals. Mange in domestic animals is caused by the same organism. Infection usually affects the interdigital and popliteal folds, axillary folds, the umbilicus, and the scrotum.[89–92]

Clinical Presentation

Patients will complain of severe itching and an inability to sleep and may have excoriations in the interdigital web spaces, wrists, elbows, buttocks, groin, and scalp. Excoriations may lead to secondary bacterial infections. The diagnosis is made by looking for burrows formed by the mite and taking skin scrapings, which will demonstrate the mite on a wet mount.

TREATMENT

Scabies

Because these infections cause a great deal of discomfort and distress to patients and families, the goals of therapy are to eradicate the infestations rapidly, to institute symptomatic treatment, and to provide counseling and reassurance. The treatment of choice is permethrin 5% (Elimite) cream.[16,90–92] To initiate the treatment, the skin should be scrubbed thoroughly in a warm soapy bath using a soft brush to remove all scabs. The lotion is then applied to the whole body, avoiding the face, mucous membranes, and eyes. The application should be left on for 8 to 14 hours before bathing. A single application eradicates 97% of scabies in subjects.[90] All close contacts should be checked and treated appropriately.

Other agents used to treat scabies include topical crotamiton 10% (Eurax) and oral ivermectin (Stromectol) 200 mcg/kg as a single dose which may be repeated in 2 weeks.[16,92] Crotamiton and oral ivermectin may be used in patients who have hypersensitivity to permethrin preparations. Topical corticosteroids and antihistamines may be used to decrease pruritus.

10 Permethrin (1% and 5%) for pediculosis and scabies, respectively, is the preferred agent and remains the safest agent, especially in infants and children.[84,92] One application of permethrin is consistently effective in eradicating more than 90% of all infections. However, pruritus may persist for 2 to 4 weeks because of the remnants of mite parts in the skin. Ivermectin is an alternative therapy for scabies.

ABBREVIATIONS

AIDS: acquired immunodeficiency syndrome

ELISA: enzyme-linked immunosorbent assay

PCR: polymerase chain reaction

Appendix 124-1 Antiparasitic Drugs

Drug	Indications	Side Effects	Comments	References
Albendazole 200 mg tablet (Albenza)	Giardiasis, Ascariasis, Neurocysticercosis	GI: abdominal pain, nausea, diarrhea, increase in liver function enzymes	Not recommended in children <2 years old	9, 16, 42, 45, 46
Artemether 20 mg/Lumefantrine 120 mg tablet (Coartem	Acute uncomplicated Falciparum malaria	Headache, dizziness, asthenia, fatigue, and arthralgia	Approved for patients >5 kg body weight	52, 75
Artesunate[a]	Severe *falciparum* malaria	Rash, dizziness, and pruritus	Obtained by IND from CDC (when IV Quinidine is not readily available)	16, 58
Atovaquone 250 mg *plus* proguanil 100 mg (Malarone)[b]	Prevention and treatment of *Plasmodium falciparum* malaria	Abdominal pain, nausea, vomiting, and headache		9, 16, 48, 49, 52, 61, 62, 75
Chloroquine phosphate (Aralen, Nivaquine) 250- and 500-mg tablets; 50 mg/mL (as HCl); 5-mL ampule	Malaria	GI: nausea, vomiting, diarrhea CNS: dizziness, headache, blurring of vision, confusion, fatigue Derm: pruritus	Administer oral dose after meals IV route: recommend ECG monitoring *Contraindication*: patients with psoriasis or porphyria	9, 16, 48, 49, 52, 61, 62, 75
Diloxanide furoateb (Furamide) 500-mg tablet[c]	Amebiasis	GI: nausea, flatulence Derm: pruritus		9, 16, 19, 20, 21, 23, 75
Furazolidone (Furoxone) 100-mg tablet Suspension: 50 mg/5 mL	Giardiasis Alternative to metronidazole	GI: nausea, vomiting Hypersensitivity: hypotension, fever, arthralgia, urticaria Other: headache	Disulfiram-like reaction with alcohol; avoid in G6PD deficiency; may cause hemolysis; changes color of urine to brown	9,16
Iodoquinol (Yodoxin) 210-mg tablet	Amebiasis	GI: abdominal pain, diarrhea Derm: rash	May interfere with thyroid function test *Contraindication*: patients with iodine intolerance	9, 16, 19–23, 75
Ivermectin (Stromectol) 6-mg tablet	Strongyloidiasis Pediculosis Scabies	Dizziness, somnolence, tremor, vertigo, pruritus, abdominal pain	Should be taken with a full glass of water	9, 16, 34, 37, 39, 92
Mebendazole (Vermox) 100-mg chewable tablet	Ascariasis, trichuriasis, hookworm, pinworm	GI: abdominal pain, diarrhea CNS: headache, dizziness Other: pyrexia, neutropenia	Drug should be taken with meals *Contraindication*: pregnancy *Drug interaction*: can increase serum levels of theophylline	9, 16, 25, 26
Mefloquine (Lariam) 250-mg tablet	*P falciparum* malaria	Incidence 17% GI: nausea, vomiting, abdominal pain, diarrhea Card: sinus bradycardia CNS: vertigo, dizziness, confusion, hallucinations, psychosis, convulsions Derm: itching, skin rash	Patients given doses in excess of 12 mg/kg should be monitored carefully because the side effects are dose related	9, 16, 48–50, 52, 55, 61, 62, 75
Metronidazole (Flagyl) Oral: 250-mg, 500-mg tablets	Amebiasis Giardiasis	GI: nausea, anorexia, vomiting, diarrhea, abdominal cramping, glossitis, metallic taste CNS: dizziness, vertigo, headache, paresthesia	Avoid alcohol; alcohol ingestion will cause the disulfiram reaction: abdominal distress, vomiting, hypotension *Contraindication*: First trimester of pregnancy	9, 11–13, 16,19–21
Nifurtimox[c] (Lampit, Bayer 2502)	South American trypanosomiasis	GI: anorexia, nausea CNS: peripheral neuritis, psychosis Hemat: hemolysis in G6PD deficiency patients	Monitor pulmonary function and hematologic parameters	9, 16, 75, 76, 78, 79
Nitazoxanide (Alinia) 100-mg/5-mL suspension	Cryptosporidiosis Giardiasis	Abdominal pain, diarrhea, vomiting, and headache	Rarely may produce yellow sclerae	12, 16, 17
Primaquine phosphate 26.3-mg tablet	Malaria *(P vivax) (P ovale)*	GI: nausea, abdominal pain CNS: mental depression	In G6PD deficiency can cause hemolysis	9, 16, 48, 49, 52, 55, 62

(continued)

Appendix 124-1 Antiparasitic Drugs (continued)

Drug	Indications	Side Effects	Comments	References
Pyrimethamine 25 mg *plus* sulfadoxine 500 mg (Fansidar)	*P falciparum*-resistant malaria	GI: nausea, abdominal pain, stomatitis, headache, and glossitis Hemat: agranulocytosis, aplastic anemia, leukopenia, megaloblastic anemia, hemolytic anemia, hemolysis in patients with G6PD deficiency	Combination was recently reported to cause the Stevens-Johnson syndrome; patients should be advised to call their physician/ pharmacist if a skin rash or other reaction is seen	9, 16, 48, 49, 75
Quinacrine 100 mg[c]	Giardiasis	GI: nausea, anorexia, vomiting Headache, toxic psychosis, hepatitis, and aplastic anemia	Avoid in pregnancy, psychosis, and psoriasis	9, 12, 16
Quinidine gluconate 500 mg base/mL; 10 mL	Acute malaria	GI: nausea, vomiting, diarrhea Card: hypotension, widening of QRS and QT on ECG, heart block	Administration of IV quinidine requires close monitoring; should normally monitor ECG and all vital signs	9, 16, 48, 49, 52
Quinine sulfate 325-mg and 650-mg tablets	Acute malaria	Cinchonism: flushing, dizziness, nausea, vomiting, diarrhea (levels over 10 mcg/mL) Card: hypotension, widening of QRS complex Hemat: hemolysis, leukopenia, thrombocytopenia	When drug is administered IV, it should be administered by slow infusion (600 mg over 8 hours); close monitoring of vitals and ECG *Avoid use*: IM administration	9, 16, 48, 49, 52, 55

Card, cardiologic; Derm, dermatologic; ECG, elecetrocardiogram; G6PD, glucose-6-phosphate dehydrogenase; Hemat, hematologic; IND, investigational new drug.

CHAPTER 125

Urinary Tract Infections and Prostatitis

ELIZABETH A. COYLE AND RANDALL A. PRINCE

KEY CONCEPTS

1. Urinary tract infections (UTIs) are classified as uncomplicated and complicated. *Uncomplicated* refers to an infection in an otherwise healthy female who lacks structural or functional abnormalities of the urinary tract. Most often complicated infections are associated with a predisposing lesion of the urinary tract; however, the term may be used to refer to all other infections, except for those in the otherwise healthy adult female.
2. Recurrent UTIs are considered either reinfections or relapses. Reinfection usually happens more than 2 weeks after the last UTI, and is treated as a new uncomplicated UTI. Relapse usually happens within 2 weeks of the original infection and is a relapse of the original infection either because of unsuccessful treatment of the original infection, a resistant organism, or anatomical abnormalities.
3. Eighty-five percent of uncomplicated urinary tract infections are caused by *Escherichia coli*, and the remainder are caused primarily by *Staphylococcus saprophyticus, Proteus* spp., and *Klebsiella* spp. Complicated infections are more frequently associated with gram-negative organisms and *Enterococcus faecalis*.
4. Symptoms of lower urinary tract infections include dysuria, urgency, frequency, nocturia, and suprapubic heaviness, whereas upper urinary tract infections involve more systemic symptoms such as fever, nausea, vomiting, and flank pain.
5. Significant bacteriuria traditionally has been defined as bacterial counts of greater than 100,000 (10^5)/mL of urine. Many clinicians, however, have challenged this as too general a statement. Indeed, significant bacteriuria in patients with symptoms of a urinary tract infection may be defined as greater than 10^2 organisms per milliliter.
6. The goals of treatment of urinary tract infections are to eradicate the invading organism(s), prevent or treat systemic consequences of infections, and prevent the recurrence of infection.
7. Uncomplicated urinary tract infections can be managed most effectively with short-course (3 days) therapy with either trimethoprim-sulfamethoxazole or a fluoroquinolone. Complicated infections require longer treatment periods (2 weeks) usually with one of these agents.
8. In choosing appropriate antibiotic therapy, practitioners need to be cognizant of antibiotic resistance patterns, particularly to *E. coli*. Trimethoprim-sulfamethoxazole has demonstrated diminished activity against *E. coli* in some areas of the country, with reported resistance in some areas almost 30%.
9. Acute bacterial prostatitis can be managed with many agents that have activity against the causative organism. Chronic prostatitis requires an agent that is not only active against the causative organism but also concentrates in the prostatic secretions. Therapy with trimethoprim-sulfamethoxazole or a fluoroquinolone is preferred for 4 to 6 weeks.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Infections of the urinary tract represent a wide variety of syndromes, including urethritis, cystitis, prostatitis, and pyelonephritis. Urinary tract infections (UTIs) are the most commonly occurring bacterial infections, especially in females of child-bearing age.[1–3] Approximately 60% of females will develop a UTI during their lifetime, with about one fourth having a recurrence within a year.[2] Infections in men occur much less frequently until the age of 65 years, at which point the incidence rates in men and women are similar.

A UTI is defined as the presence of microorganisms in the urinary tract that cannot be accounted for by contamination. The organisms present have the potential to invade the tissues of the urinary tract and adjacent structures. Infection may be limited to the growth of bacteria in the urine, which frequently may not produce symptoms. A UTI can present as several syndromes associated with an inflammatory response to microbial invasion and can range from asymptomatic bacteriuria to pyelonephritis with bacteremia or sepsis.

UTIs are classified by lower and upper urinary tract infections. Typically, they have been described by anatomic site of involvement. Lower tract infections correspond to cystitis (bladder), and pyelonephritis (an infection involving the kidneys) represents upper tract infection.

1 Also, UTIs are designated as uncomplicated or complicated. Uncomplicated infections occur in individuals who lack structural or functional abnormalities of the urinary tract that interfere with the normal flow of urine or voiding mechanism. These infections occur in females of child-bearing age (15 to 45 years) who are otherwise normal, healthy individuals. Infections in males generally are not classified as uncomplicated because these infections are rare and most often represent a structural or neurologic abnormality.

Complicated UTIs are the result of a predisposing lesion of the urinary tract, such as a congenital abnormality or distortion of the urinary tract, a stone, indwelling catheter, prostatic hypertrophy, obstruction, or neurologic deficit that interferes with the normal

TABLE 125-1 Diagnostic Criteria for Significant Abacteriuria

$\geq 10^2$ CFU coliforms/mL or $\geq 10^5$ CFU noncoliforms/mL in a symptomatic female
$\geq 10^3$ CFU bacteria/mL in a symptomatic male
$\geq 10^5$ CFU bacteria/mL in asymptomatic individuals on two consecutive specimens
Any growth of bacteria on suprapubic catheterization in a symptomatic patient
$\geq 10^2$ CFU bacteria/mL in a catheterized patient

CFU, colony-forming unit.

flow of urine and urinary tract defenses. Complicated infections occur in both genders and frequently involve the upper and lower urinary tract.

2 Recurrent UTIs in healthy nonpregnant women—three or more UTIs occurring within 1 year—are a common problem. They are characterized by multiple symptomatic infections with asymptomatic periods occurring between each episode and may be either reinfections or relapses. Reinfections are caused by a different organism than originally isolated and account for the majority of recurrent UTIs. Relapses are the development of repeated infections with the same initial organism and usually indicate a persistent infectious source.[2]

Asymptomatic bacteriuria is a common finding, particularly among those 65 years of age and older, when there is significant bacteriuria (>10^5 bacteria/mL of urine) in the absence of symptoms. Symptomatic abacteriuria or acute urethral syndrome consists of symptoms of frequency and dysuria in the absence of significant bacteriuria. This syndrome is commonly associated with *Chlamydia* infections.

Significant abacteriuria is a term used to distinguish the presence of microorganisms that represent true infection versus contamination of the urine as it passes through the distal urethra prior to collection. Historically, bacterial counts equal to or greater than 100,000 organisms/mL of urine in a "clean-catch" specimen were judged to indicate true infection.[4–6] Counts less than 100,000 organisms/mL of urine, however, may represent true infection in certain situations. For example, with concurrent antibacterial drug administration, rapid urine flow, low urinary pH, or upper tract obstruction.[6] Table 125–1 lists the clinical definitions of significant bacteriuria, which are dependent on the clinical setting and the method of specimen collection.[6] These criteria allow for more appropriate specificity and sensitivity in documenting infection under differing clinical circumstances.

EPIDEMIOLOGY

The prevalence of UTIs varies with age and gender. In newborns and infants up to 6 months of age, the prevalence of abacteriuria is approximately 1% and is more common in boys. Most of these infections are associated with structural or functional abnormalities of the urinary tract and also have been correlated with noncircumcision.[7] Between the ages of 1 and 6 years, UTIs occur more frequently in females. The prevalence of abacteriuria in females and males of this age group is 7% and 2%, respectively.[7,8] Infections occurring in preschool boys usually are associated with congenital abnormalities of the urinary tract. These infections are difficult to recognize because of the age of the patient, but they often are symptomatic. In addition, the majority of renal damage associated with UTI develops at this age.[7,8]

Through grade school and before puberty, the prevalence of UTI is approximately 1%, with 5% of females reported to have significant bacteriuria prior to leaving high school. This percentage increases dramatically to 1% to 4% after puberty in nonpregnant females primarily as a result of sexual activity. Approximately 1 in 5 women will suffer a symptomatic UTI at some point in their lives. Many women have recurrent infections, with a significant proportion of these women having a history of childhood infections. In contrast, the prevalence of bacteriuria in adult men is very low (<0.1%).[9]

In the elderly, the ratio of bacteriuria in women and men is dramatically altered and is approximately equal in persons older than age 65 years.[10] The overall incidence of UTI increases substantially in this population, with the majority of infections being asymptomatic. The rate of infection increases further for elderly persons who are residing in nursing homes, particularly those who are hospitalized frequently. The increase is probably the result of factors such as obstruction from prostatic hypertrophy in males, poor bladder emptying as a result of prolapse in females, fecal incontinence in demented patients, neuromuscular disease including strokes, and increased urinary instrumentation (catheterization).

ETIOLOGY

3 The bacteria causing UTIs usually originate from bowel flora of the host. Although virtually every organism is associated with UTIs, certain organisms predominate as a result of specific virulence factors. The most common cause of uncomplicated UTIs is *Escherichia coli*, which accounts for 80% to 90% of community-acquired infections. Additional causative organisms in uncomplicated infections include *Staphylococcus saprophyticus*, *Klebsiella pneumoniae, Proteus* spp., *Pseudomonas aeruginosa*, and *Enterococcus* spp.[11] Because *Staphylococcus epidermidis* is frequently isolated from the urinary tract, it should be considered initially a contaminant. Repeat cultures should be performed to help confirm the organism as a real pathogen.

Organisms isolated from individuals with complicated infections are more varied and generally are more resistant than those found in uncomplicated infections. *E. coli* is a frequently isolated pathogen, but it accounts for less than 50% of infections. Other frequently isolated organisms include *Proteus* spp., *K. pneumoniae, Enterobacter* spp., *P. aeruginosa*, staphylococci, and enterococci. Enterococci represent the second most frequently isolated organisms in hospitalized patients.[11,12] In part, this finding may be related to the extensive use of third-generation cephalosporin antibiotics, which are not active against the enterococci. Vancomycin-resistant *Enterococcus faecalis* and *Enterococcus faecium* (vancomycin-resistant enterococci) have become more widespread, especially in patients with long-term hospitalizations or underlying malignancies. Vancomycin-resistant enterococci are major therapeutic and infection control issues because the organisms are susceptible to few antimicrobials.[12]

Staphylococcus aureus infections may arise from the urinary tract, but they are more commonly a result of bacteremia producing metastatic abscesses in the kidney. *Candida* spp. are common causes of UTI in the critically ill and chronically catheterized patient.

Most UTIs are caused by a single organism; however, in patients with stones, indwelling urinary catheters, or chronic renal abscesses, multiple organisms may be isolated. Depending on the clinical situation, the recovery of multiple organisms may represent contamination, and a repeat evaluation should be done.

PATHOPHYSIOLOGY

ROUTE OF INFECTION

Organisms typically gain entry into the urinary tract via three routes: the ascending, hematogenous (descending), and lymphatic pathways. The female urethra usually is colonized by bacteria believed to originate from the fecal flora. The short length of the female urethra and its proximity to the perirectal area make

colonization of the urethra likely. Other factors that promote urethral colonization include the use of spermicides and diaphragms as methods of contraception.[2,3] Although there is evidence in females that bladder infections follow colonization of the urethra, the mode of ascent of the microorganisms is incompletely understood. Massage of the female urethra and sexual intercourse allow bacteria to reach the bladder.[13] Once bacteria have reached the bladder, the organisms quickly multiply and can ascend the ureters to the kidneys. This sequence of events is more likely to occur if vesicoureteral reflux (reflux of urine into the ureters and kidneys while voiding) is present. UTIs are more common in females than in males because the anatomic differences in location and length of the urethra tend to support the ascending route of infections as the primary acquisition route.

Infection of the kidney by hematogenous spread of microorganisms usually occurs as the result of dissemination of organisms from a distant primary infection in the body. Infections via the descending route are uncommon and involve a relatively small number of invasive pathogens. Bacteremia caused by *S. aureus* may produce renal abscesses. Additional organisms include *Candida* spp., *Mycobacterium tuberculosis, Salmonella* spp., and enterococci. Of particular interest, it is difficult to produce experimental pyelonephritis by intravenously administering common gram-negative organisms such as *E. coli* and *P. aeruginosa*. Overall, less than 5% of documented UTIs result from hematogenous spread of microorganisms.

There appears to be little evidence supporting a significant role for renal lymphatics in the pathogenesis of UTIs. There are lymphatic communications between the bowel and kidney, as well as between the bladder and kidney. There is no evidence, however, that microorganisms are transferred to the kidney via this route.

After bacteria reach the urinary tract, three factors determine the development of infection: the size of the inoculum, the virulence of the microorganism, and the competency of the natural host defense mechanisms. Most UTIs reflect a failure in host defense mechanisms.

HOST DEFENSE MECHANISMS

The normal urinary tract generally is resistant to invasion by bacteria and is efficient in rapidly eliminating microorganisms that reach the bladder. The urine under normal circumstances is capable of inhibiting and killing microorganisms. The factors thought to be responsible include a low pH, extremes in osmolality, high urea concentration, and high organic acid concentration. Bacterial growth is further inhibited in males by the addition of prostatic secretions.[14,15]

The introduction of bacteria into the bladder stimulates micturition, with increased diuresis and efficient emptying of the bladder. These factors are critical in preventing the initiation and maintenance of bladder infections. Patients who are unable to void urine completely are at greater risk of developing UTIs and frequently have recurrent infections. Also, patients with even small residual amounts of urine in their bladder respond less favorably to treatment than patients who are able to empty their bladders completely.[16]

An important virulence factor of bacteria is their ability to adhere to urinary epithelial cells, resulting in colonization of the urinary tract, bladder infections, and pyelonephritis. Various factors that act as antiadherence mechanisms are present in the bladder, preventing bacterial colonization and infection. The epithelial cells of the bladder are coated with a urinary mucus or slime called *glycosaminoglycan*. This thin layer of surface mucopolysaccharide is hydrophilic and strongly negatively charged. When bound to the uroepithelium, it attracts water molecules and forms a layer between the bladder and urine. The antiadherence characteristics of the glycosaminoglycan layer are nonspecific, and when the layer is removed by dilute acid solutions, rapid bacterial adherence results.[17]

In addition, the Tamm-Horsfall protein is a glycoprotein produced by the ascending limb of Henle and distal tubule that is secreted into the urine and contains mannose residues. These mannose residues bind *E. coli* that contain small surface-projecting organellae on their surfaces called *pili* or *fimbriae*. Type 1 fimbriae are mannose sensitive, and this interaction prevents the bacteria from binding to similar receptors present on the mucosal surface of the bladder. Other factors that possibly prevent adherence of bacteria include immunoglobulins (Ig) G and A. Investigators have documented both systemic and local kidney immunoglobulin synthesis in upper tract infections. The role of immunoglobulins in preventing bladder infection is less clear. Patients with reduced urinary levels of secretory IgA are, however, at increased risk of infections of the urinary tract.

After bacteria actually have invaded the bladder mucosa, an inflammatory response is stimulated with the mobilization of polymorphonuclear leukocytes (PMNs) and resulting phagocytosis. PMNs are primarily responsible for limiting the tissue invasion and controlling the spread of infection in the bladder and kidney. They do not play a role in preventing bladder colonization or infections and actually contribute to renal tissue damage.

Other host factors that may play a role in the prevention of UTIs are the presence of *Lactobacillus* in the vaginal flora and circulating estrogen levels. In premenopausal women, circulating estrogen supports the vaginal tract growth of lactobacilli, which produce lactic acid to help maintain a low vaginal pH, thereby preventing *E. coli* vaginal colonization.[18] Topical estrogens are used for the prevention of UTI in postmenopausal women who have more than 3 recurrent UTI episodes per year and are not on oral estrogens.[19]

BACTERIAL VIRULENCE FACTORS

Pathogenic organisms have differing degrees of pathogenicity (virulence), which play a role in the development and severity of infection. Bacteria that adhere to the epithelium of the urinary tract are associated with colonization and infection. The mechanism of adhesion of gram-negative bacteria, particularly *E. coli*, is related to bacterial fimbriae that are rigid, hair-like appendages of the cell wall.[9] These fimbriae adhere to specific glycolipid components on epithelial cells. The most common type of fimbriae is type 1, which binds to mannose residues present in glycoproteins. Glycosaminoglycan and Tamm-Horsfall protein are rich in mannose residues that readily trap those organisms that contain type 1 fimbriae, which are then washed out of the bladder.[20] Other fimbriae are mannose resistant and are associated more frequently with pyelonephritis, such as P fimbriae, which bind avidly to specific glycolipid receptors on uroepithelial cells. These bacteria are resistant to washout or removal by glycosaminoglycan and are able to multiply and invade tissue, especially the kidney. In addition, PMNs, as well as secretory IgA antibodies, contain receptors for type 1 fimbriae, which facilitate phagocytosis, but they lack receptors for P fimbriae.

Other virulence factors include the production of hemolysin and aerobactin.[21] Hemolysin is a cytotoxic protein produced by bacteria that lyses a wide range of cells, including erythrocytes, PMNs, and monocytes. *E. coli* and other gram-negative bacteria require iron for aerobic metabolism and multiplication. Aerobactin facilitates the binding and uptake of iron by *E. coli;* however, the significance of this property in the pathogenesis of UTIs remains unknown.

PREDISPOSING FACTORS TO INFECTION

The normal urinary tract typically is resistant to infection and colonization by pathogenic bacteria. In patients with underlying structural abnormalities of the urinary tract, the typical host

defenses previously discussed usually are lacking. There are several known abnormalities of the urinary tract system that interfere with its natural defense mechanisms, the most important of which is obstruction. Obstruction can inhibit the normal flow of urine, disrupting the natural flushing and voiding effect in removing bacteria from the bladder and resulting in incomplete emptying. Common conditions that result in residual urine volumes include prostatic hypertrophy, urethral strictures, calculi, tumors, bladder diverticula, and drugs such as anticholinergic agents. Additional causes of incomplete bladder emptying include neurologic malfunctions associated with stroke, diabetes, spinal cord injuries, tabes dorsalis, and other neuropathies. Vesicoureteral reflux represents a condition in which urine is forced up the ureters to the kidneys. Urinary reflux is associated not only with an increased incidence of UTIs and pyelonephritis, but also with renal damage.[8,16] Reflux may be the result of a congenital abnormality or, more commonly, bladder overdistension from obstruction.

Other risk factors include urinary catheterization, mechanical instrumentation, pregnancy, and the use of spermicides and diaphragms.

CLINICAL PRESENTATION

4 The presenting signs and symptoms of UTIs in adults are recognized easily (Table 125–2). Women frequently will report gross hematuria. Systemic symptoms, including fever, typically are absent in this setting. Unfortunately, large numbers of patients with significant bacteriuria are asymptomatic. These patients may be normal, healthy patients, elderly patients, children, pregnant patients, and patients with indwelling catheters. It is important to note that attempts at differentiating upper tract from lower tract infections on the basis of symptoms alone are not reliable.

Elderly patients frequently do not experience specific urinary symptoms, but they will present with altered mental status, change in eating habits, or gastrointestinal symptoms. In addition, patients with indwelling catheters or neurologic disorders commonly will not have lower tract symptoms, whereas flank pain and fever may be recognized. Many of the aforementioned patients, however, frequently will develop upper tract infections with bacteremia and no or minimal urinary tract symptoms.

Symptoms alone are unreliable for the diagnosis of bacterial UTIs. The key to the diagnosis of UTI is the ability to demonstrate significant numbers of microorganisms in an appropriate urine specimen to distinguish contamination from infection. The type and extent of laboratory examination required depends on the clinical situation.

TABLE 125-2 Clinical Presentation of Urinary Tract Infections in Adults

Signs and symptoms
Lower UTI: dysuria, urgency, frequency, nocturia, suprapubic heaviness
Gross hematuria
Upper UTI: flank pain, fever, nausea, vomiting, malaise
Physical examination
Upper UTI: costovertebral tenderness
Laboratory tests
Bacteriuria
Pyuria (white blood cell count >10/mm^3)
Nitrite-positive urine (with nitrite reducers)
Leukocyte esterase-positive urine
Antibody-coated bacteria (upper UTI)

UTI, urinary tract infection.

URINE COLLECTION

Examination of the urine is the cornerstone of laboratory evaluation for UTIs. There are three acceptable methods of urine collection. The first is the *midstream clean-catch method*. After cleaning the urethral opening area in both men and women, 20 to 30 mL of urine is voided and discarded. The next part of the urine flow is collected and should be processed immediately (refrigerated as soon as possible). Specimens that are allowed to sit at room temperature for several hours may result in falsely elevated bacterial counts. The midstream clean-catch is the preferred method for the routine collection of urine for culture. When a routine urine specimen cannot be collected or contamination occurs, alternative collection techniques must be used.

The two acceptable alternative methods include catheterization and suprapubic bladder aspiration. Catheterization may be necessary for patients who are uncooperative or who are unable to void urine. If catheterization is performed carefully with aseptic technique, the method yields reliable results. Note, however, that introduction of bacteria into the bladder may result, and the procedure is associated with infection in 1% to 2% of patients. Suprapubic bladder aspiration involves inserting a needle directly into the bladder and aspirating the urine. This procedure bypasses the contaminating organisms present in the urethra, and any bacteria found using this technique generally are considered to represent significant bacteriuria.[24,25] Suprapubic aspiration is a safe and painless procedure that is most useful in newborns, infants, paraplegics, seriously ill patients, and others in whom infection is suspected and routine procedures have provided confusing or equivocal results.

BACTERIAL COUNT

5 The diagnosis of UTI is based on the isolation of significant numbers of bacteria from a urine specimen. Microscopic examination of a urine sample is an easy-to-perform and reliable method for the presumptive diagnosis of bacteriuria. The examination may be performed by preparing a Gram stain of unspun or centrifuged urine. The presence of at least one organism per oil-immersion field in a properly collected uncentrifuged specimen correlates well with more than 100,000 colony-forming units (CFU)/mL (10^5 CFU/mL) of urine. For detecting smaller numbers of organisms, a centrifuged specimen is more sensitive. Such examinations detect more than 10^5 bacteria/mL with a sensitivity of greater than 90% and a specificity of greater than 70%.[22,23] A quantitative count of greater than or equal to 10^5 CFU/mL is considered indicative of a UTI; however, up to 50% of women will present with clinical symptoms of a UTI with lower counts (10^3 CFU/mL).[4]

PYURIA, HEMATURIA, AND PROTEINURIA

Microscopic examination of the urine for leukocytes is also used to determine the presence of pyuria. The presence of pyuria in a symptomatic patient correlates with significant bacteriuria.[24] Pyuria is defined as a white blood cell (WBC) count of greater than 10 WBC/mm^3 of urine. A count of 5 to 10 WBC/mm^3 is accepted as the upper limit of normal. It should be emphasized that pyuria is nonspecific and signifies only the presence of inflammation and not necessarily infection. Thus patients with pyuria may or may not have infection. Sterile pyuria has long been associated with urinary tuberculosis, as well as chlamydial and fungal urinary infections.

Hematuria, microscopic or gross, is frequently present in patients with UTI but is nonspecific. Hematuria may indicate the presence of other disorders, such as renal calculi, tumors, or glomerulonephritis. Proteinuria is found commonly in the presence of infection.

CHEMISTRY

Several biochemical tests have been developed for screening urine for the presence of bacteria. A common dipstick test detects the presence of nitrite in the urine, which is formed by bacteria that reduce nitrate normally present in the urine. False-positive tests are uncommon. False-negative tests are more common and frequently are caused by the presence of gram-positive organisms or *P. aeruginosa* that do not reduce nitrate.[25] Other causes of false tests include low urinary pH, frequent voiding, and dilute urine.

The leukocyte esterase dipstick test is a rapid screening test for detecting the presence of pyuria. Leukocytes esterase is found in primary neutrophil granules and indicates the presence of WBCs. The leukocyte esterase test is a sensitive and highly specific test for detecting more than 10 WBC/mm^3 of urine. When the leukocyte esterase test is used with the nitrite test, the reported positive predictive value and specificity is 79% and 82%, respectively, for the detection of bacteriuria.[27] These tests can be useful in the outpatient evaluation of uncomplicated UTIs. However, urine culture is still the "gold standard" test in determining the presence of UTIs.

CULTURE

The most reliable method of diagnosing UTI is by quantitative urine culture. Urine in the bladder is normally sterile, making it statistically possible to differentiate contamination of the urine from infection by quantifying the number of bacteria present in a urine sample. This criterion is based on a properly collected midstream clean-catch urine specimen. Patients with infection usually have greater than 10^5 bacteria/mL of urine. It should be emphasized that as many as one third of women with symptomatic infection have less than 10^5 bacteria/mL. A significant portion of patients with UTIs, either symptomatic or asymptomatic, also have less than 10^5 bacteria/mL of urine.

Several laboratory methods are used to quantify bacteria present in the urine. The most accurate method is the pour-plate technique. This method is unsuitable for a high-volume laboratory because it is expensive and time-consuming. The streak-plate method is an alternative that involves using a calibrated-loop technique to streak a fixed amount of urine on an agar plate. This method is used most commonly in diagnostic laboratories because it is simple to perform and less costly.

After identification and quantification are complete, the next step is to determine the susceptibility of the organism. There are several methods by which bacterial susceptibility testing may be performed. Knowledge of bacterial susceptibility and achievable urine concentration of the antibiotics puts the clinician in a better position to select an appropriate agent for treatment.

Infection Site

Several methods have been evaluated to determine the location of infection within the urinary system and differentiate upper tract from lower tract involvement. The most direct method is a ureteral catheterization procedure as described by Stamey and colleagues.[28] The method involves the passage of a catheter into the bladder and then into each ureter, where quantitative cultures are obtained. History and physical examination were of little value in predicting the site of infection. Although this method provides direct quantitative evidence for UTI, it is invasive, technically difficult, and expensive. The Fairley bladder washout technique is a modification of the Stamey procedure that involves Foley catheterization only.[29] After the catheter is passed into the bladder, bladder samples are obtained, and the bladder is washed out, with culture samples taken at 10, 20, and 30 minutes. The procedure shows that up to 50% of patients have renal involvement regardless of signs and symptoms. Other investigators found 10% to 20% of tests to be equivocal.[29]

Noninvasive methods of localization may be more acceptable for routine use; however, they have limited clinical value. Patients with pyelonephritis can have abnormalities in urinary concentrating ability. The use of concentrating ability for localization of UTIs, however, is associated with high false-positive and false-negative responses and is not useful clinically.[25] The antibody-coated bacteria test is an immunofluorescent method that detects bacteria coated with Ig in freshly voided urine, indicating upper urinary tract infection. The sensitivity and specificity of this test to localize the site of infection are reported to average 88% and 76%, respectively.[30] Because of the high incidence of false-positive and false-negative results, antibody-coated bacteria testing is not used routinely in the management of UTIs.

Virtually all patients with uncomplicated lower tract infections can be cured with a short course of antibiotic therapy, and this assumption sometimes can be used to distinguish between patients with lower and upper tract infections. Patients who do not respond or who relapse do so because of upper tract involvement. It is rarely necessary to localize the site of infection to direct the clinical management of such patients.

TREATMENT

DESIRED OUTCOME

6 The goals of UTI treatments are (a) to eradicate the invading organism(s), (b) to prevent or to treat systemic consequences of infection, and (c) to prevent the recurrence of infection.

MANAGEMENT

The management of a patient with a UTI includes initial evaluation, selection of an antibacterial agent and duration of therapy, and followup evaluation. The initial selection of an antimicrobial agent for the treatment of UTI is based primarily on the severity of the presenting signs and symptoms, the site of infection, and whether the infection is determined to be uncomplicated or complicated. Other considerations include antibiotic susceptibility, side-effect potential, cost, and the comparative inconvenience of different therapies.

Various pharmacologic factors may affect the action of antibacterial agents. Certainly, the ability of the agent to achieve appropriate concentrations in the urine is of utmost importance. Factors that affect the rate and extent of excretion through the kidney include the patient's glomerular filtration rate and whether or not the agent is actively secreted. Filtration depends on the molecular size and degree of protein binding of the agent. Agents such as sulfonamides, tetracyclines, and aminoglycosides enter the urine via filtration. As the glomerular filtration rate is reduced, the amount of drug that enters the urine is reduced. Most β-lactam agents and quinolones are filtered and are actively secreted into the urine. For this reason, these agents achieve high urinary concentrations despite unfavorable protein-binding characteristics or the presence of renal dysfunction.

The ability to eradicate bacteria from the urine is related directly to the sensitivity of the microorganism and the achievable concentrations of the antimicrobial agent in the urine. Unfortunately, most susceptibility testing is directed at achievable concentrations in the blood. There is a poor correlation between achievable blood levels of antimicrobial agents and the eradication of bacteria from the urine.[31] In the treatment of lower tract infections, plasma concentrations of antibacterial agents may not be important, but achieving appropriate plasma concentrations appears critical in patients with bacteremia and renal abscesses.

Nonspecific therapies have been advocated in the treatment and prevention of UTIs. Fluid hydration has been used to produce rapid dilution of bacteria and removal of infected urine by increased voiding. A critical factor appears to be the amount of residual volume remaining after voiding. As little as 10 mL of residual urine can alter the eradication of infection significantly.[16] Paradoxically, increased diuresis also may promote susceptibility to infection by diluting the normal antibacterial properties of the urine. Often in clinical practice the concentrations of antimicrobial agents in the urine are so high that dilution has little effect on efficacy.

The antibacterial activity of the urine is related to the low pH, which is the result of high concentrations of various organic acids. Large volumes of cranberry juice increase the antibacterial activity of the urine and prevent the development of UTIs.[3,32–34] Apparently, the fructose and other unknown substances (condensed tannins) in cranberry juice act to interfere with adherence mechanisms of some pathogens, thereby preventing infection. Acidification of the urine by cranberry juice does not appear to play a significant role. The use of other agents (ascorbic acid) to acidify the urine to hinder bacterial growth does not achieve significant acidification. Consequently, attempts to acidify urine with systemic agents are not recommended. *Lactobacillus* probiotics also may aid in the prevention of female UTIs by decreasing the vaginal pH, thereby decreasing *E. coli* colonization.[19,33] In postmenopausal women, estrogen replacement may be of help in the prevention of recurrent UTIs. After 1 month of topical estrogen replacement, decreases in vaginal *Lactobacillus*, as well as decreases in vaginal pH and *E. coli* colonization, have been found.[18,33]

Urinary analgesics such as phenazopyridine hydrochloride are used frequently by many clinicians.[3] If the pain or dysuria present in a UTI is a consequence of infection, then urinary analgesics have little clinical role because most patients' symptoms respond quite rapidly to appropriate antibacterial therapy. Urinary analgesics also may mask signs and symptoms of UTIs not responding to antimicrobial therapy.

CLINICAL CONTROVERSY

The role of nonantibiotic alternatives such as cranberry juice, estrogens, and lactobacilli in the prevention of urinary tract infections has long been discussed. Lactobaccillus potentially helps keep the vaginal pH in the normal range (pH 4–4.5), regulating genitourinary bacteria assisting in the prevention of UTIs.[33] Possible clinical benefits with cranberry juice in sexually active adult women with recurrent UTI have been suggested. However, the consistency of study results has varied, as have the types of cranberry products tested, leading to inconclusive evidence.[32,34] In a randomized, double-blind, placebo-controlled study, postmenopausal women receiving topical estriol vaginal cream had significantly fewer UTIs than did those receiving placebo.[18,19] Estrogens are only recommended in topical formulation in postmenapausal females having ≥ 3 recurrent UTIs/year and are not taking oral estrogens.[19] More thorough studies on the overall effectiveness of cranberry juice, lactobacilli, and/or estrogen replacement needs to be performed before a uniform opinion of the role of these agents in UTIs can be formulated.

PHARMACOLOGIC THERAPY

Ideally, the antimicrobial agent chosen should be well tolerated, well absorbed, achieve high urinary concentrations, and have a spectrum of activity limited to the known or suspected pathogen(s). Table 125–3 lists the most common agents used in the treatment of UTIs along with comments concerning their general use. Table 125–4 presents an overview of various therapeutic options for outpatient therapy of UTI. Table 125–5 describes empirical treatment regimens for selected clinical situations.

8 The therapeutic management of UTIs is best accomplished by first categorizing the type of infection: acute uncomplicated cystitis, symptomatic abacteriuria, asymptomatic bacteriuria, complicated UTIs, recurrent infections, or prostatitis. In choosing the appropriate antibiotic therapy, it is important to be aware of the increasing resistance of *E. coli* and other pathogens to many frequently prescribed antimicrobials. Resistance to *E. coli* is as high as 37% for ampicillin.[35] Overall, most *E. coli* remain susceptible to trimethoprim-sulfamethoxazole, although resistance is continuing to increase and has been reported as high as 27%.[35] Although resistance to the fluoroquinolones remains low, these agents are being utilized more frequently and the incidence of fluoroquinolone-resistant *E. coli* is increasingly being reported and is of great concern.[35–40] Current or recent antibiotic exposure is the most significant risk factor associated with *E. coli* resistance, and with the extensive use of the fluoroquinolones and trimethoprim-sulfamethoxazole for various infections, including UTIs, resistance will continue to increase.[35–39] In light of rising resistance and in order to decrease the overuse of broad-spectrum antimicrobials, agents such as nitrofurantoin and fosfomycin may be reliable options in the treatment of acute uncomplicated cystitis. In addition, *E. coli* remains highly susceptible to both nitrofurantoin and fosfomycin.[3,41–45] Antibiotic therapy should be determined based on the geographic resistance patterns, as well as the patient's recent history of antibiotic exposure.

CLINICAL CONTROVERSY

The problem of antibiotic resistance is increasing in the treatment of uncomplicated urinary tract infections. The majority of infections are treated with trimethoprim-sulfamethoxazole or a fluoroquinolone; however, resistance to these agents is continuing to rise with rates as high as 29.6% and 9%, respectively.[40] These agents have very broad antimicrobial coverage, are used for various types of infections, and have a high impact on gastrointestinal flora, increasing the risk for resistant *E. coli* pathogens.[35–37,40,41] Although these agents remain highly effective in the empiric treatment of the majority of uncomplicated UTIs, the need for more selective agents for management of such infections may be warranted. Therefore, the utilization of more selective antimicrobials as first line agents, such as nitrofurantoin and fosfomycin, may become common in the coming years.[42,43]

ACUTE UNCOMPLICATED CYSTITIS

Acute uncomplicated cystitis is the most common form of UTI. These infections typically occur in women of childbearing age and often are related to sexual activity. Although the presence of dysuria, frequency, urgency, and suprapubic discomfort frequently is associated with lower tract infection, a significant number of patients have upper tract involvement as well.[3] Because these infections are predominantly caused by *E. coli*, antimicrobial therapy initially should be directed against this organism. Other common causes include *S. saprophyticus* and occasionally, *K. pneumoniae* and *Proteus mirabilis*. Because the causative organisms and their susceptibility generally are known, many clinicians advocate a cost-effective approach to management. This approach includes

TABLE 125-3 Commonly Used Antimicrobial Agents in the Treatment of Urinary Tract Infections

Agent	Comments
Oral therapy	
Trimethoprim-sulfamethoxazole	This combination is highly effective against most aerobic enteric bacteria except *Pseudomonas aeruginosa*. High urinary tract tissue levels and urine levels are achieved, which may be important in complicated infection treatment. Also effective as prophylaxis for recurrent infections.
Penicillins Ampicillin Amoxicillin-clavulanic acid	Ampicillin is the standard penicillin that has broad-spectrum activity. Increasing *Escherichia coli* resistance has limited amoxicillin use in acute cystitis. Drug of choice for enterococci sensitive to penicillin. Amoxicillin-clavulanate is preferred for resistance problems.
Cephalosporins Cephalexin Cefaclor Cefadroxil Cefuroxime Cefixime Cefprozil Cefpodoxime	There are no major advantages of these agents over other agents in the treatment of UTIs, and they are more expensive. They may be useful in cases of resistance to amoxicillin and trimethoprim–sulfamethoxazole. These agents are not active against enterococci.
Tetracyclines Tetracycline Doxycycline Minocycline	These agents have been effective for initial episodes of urinary tract infections; however, resistance develops rapidly, and their use is limited. These agents also lead to candidal overgrowth. They are useful primarily for chlamydial infections.
Fluoroquinolones Ciprofloxacin Levofloxacin	The newer quinolones have a greater spectrum of activity, including *P. aeruginosa*. These agents are effective for pyelonephritis and prostatitis. Avoid in pregnancy and children. Moxifloxacin should not be used owing to inadequate urinary concentrations.
Nitrofurantoin	This agent is effective as both a therapeutic and prophylactic agent in patients with recurrent UTIs. Main advantage is the lack of resistance even after long courses of therapy. Adverse effects may limit use (GI intolerance, neuropathies, pulmonary reactions).
Azithromycin	Single-dose therapy for chlamydial infections.
Fosfomycin	Single-dose therapy for uncomplicated infections.
Parenteral therapy	
Aminoglycosides Gentamicin Tobramycin Amikacin	Gentamicin and tobramycin are equally effective; gentamicin is less expensive. Tobramycin has better pseudomonal activity, which may be important in serious systemic infections. Amikacin generally is reserved for multiresistant bacteria.
Penicillins Ampicillin Ampicillin-sulbactam Ticarcillin-clavulanate Piperacillin-tazobactam	These agents generally are equally effective for susceptible bacteria. The extended-spectrum penicillins are more active against *P. aeruginosa* and enterococci and often are preferred over cephalosporins. They are very useful in renally impaired patients or when an aminoglycoside is to be avoided.
Cephalosporins, first-, second-, and third-generation	Second- and third-generation cephalosporins have a broad spectrum of activity against gram-negative bacteria but are not active against enterococci and have limited activity against *P. aeruginosa*. Ceftazidime and cefepime are active against *P. aeruginosa*. They are useful for nosocomial infections and urosepsis due to susceptible pathogens.
Carbapenems/Monobactams Imipenem-cilastatin Meropenem Ertapenem Doripenem	These agents have a broad spectrum of activity, including gram-positive, gram-negative, and anaerobic bacteria. Imipenem, meropenem, and doripenem are active against *P. aeruginosa* and enterococci, but ertapenem is not. All may be associated with candidal superinfections.
Aztreonam	A monobactam that is only active against gram-negative bacteria, including some strains of *P. aeruginosa*. Generally useful for nosocomial infections when aminoglycosides are to be avoided and in penicillin-sensitive patients.
Fluoroquinolones Ciprofloxacin Levofloxacin	These agents have broad-spectrum activity against both gram-negative and gram-positive bacteria. They provide urine and high-tissue concentrations and are actively secreted in reduced renal function.

a urinalysis and initiation of empirical therapy without a urine culture (Fig. 125–1).[1] Therefore, the susceptibility patterns of the geographic area drive the choice of empiric therapy, not necessarily the specific organism causing the infection.

The goal of treatment for uncomplicated cystitis is to eradicate the causative organism and to reduce the incidence of recurrence caused by relapse or reinfection. The ability to reduce the chance of recurrence depends on the agent's efficacy in eradicating the uropathogenic bacteria from the vaginal and gastrointestinal reservoir. In the past, conventional therapy consisted of an effective oral antibiotic administered for 7 to 14 days. However, acute cystitis is a superficial mucosal infection that can be eradicated with much shorter courses of therapy (3 days). Advantages of short-course therapy include increased compliance, fewer side effects, decreased cost, and less potential for the development of resistance.

7 Three-day courses of trimethoprim-sulfamethoxazole or a fluoroquinolone (e.g., ciprofloxacin or levofloxacin) are superior to single-dose therapies.[44,46–48] The fluoroquinolone moxifloxacin is not recommended for use in UTIs owing to the inadequate urinary concentrations.[49] A 5-day course of nitrofurantoin is as effective as a 3-day course of trimethoprim-sulfamethoxazole, and can be considered an alternative therapy.[50] The use of amoxicillin or amoxicillin/clavulanate is not recommended because of the high

TABLE 125-4 Overview of Outpatient Antimicrobial Therapy for Lower Tract Infections in Adults

Indications	Antibiotic	Dose[a]	Interval	Duration
Lower tract infections	Trimethoprim-sulfamethoxazole	1 DS tablet	Twice a day	3 days
Uncomplicated				
	Ciprofloxacin	250 mg	Twice a day	3 days
	Levofloxacin	250 mg	Once a day	3 days
	Amoxicillin	500 mg	Twice a day	5–7 days
	Amoxicillin-clavulanate	500 mg	Every 8 hours	5–7 days
	Trimethoprim	100 mg	Twice a day	3–5 days
	Nitrofurantoin macrocrystal	100 mg	Every 6 hours	7 days
	Nitrofurantoin monohydrate	100 mg	Twice a day	5 days
	Fosfomycin	3 g	Single dose	1 day
Complicated	Trimethoprim-sulfamethoxazole	1 DS tablet	Twice a day	7–10 days
	Ciprofloxacin	250–500 mg	Twice a day	7–10 days
	Levofloxacin	250 mg	Once a day	10 days
		750 mg	Once a day	5 days
	Amoxicillin-clavulanate	500 mg	Every 8 hours	7–10 days
Recurrent infections	Nitrofurantoin	50 mg	Once a day	6 months
	Trimethoprim-sulfamethoxazole	1/2 SS tablet	Once a day	6 months
Acute urethral syndrome	Trimethoprim-sulfamethoxazole	1 DS tablet	Twice a day	3 days
Failure of trimethoprim-sulfamethoxazole	Azithromycin	1 g	Single dose	
	Doxycycline	100 mg	Twice a day	7 days
Acute pyelonephritis	Trimethoprim-sulfamethoxazole	1 DS tablet	Twice a day	14 days
	Ciprofloxacin	500 mg	Twice a day	14 days
	Levofloxacin	250 mg	Once a day	10 days
		750 mg	Once a day	5 days
	Amoxicillin-clavulanate	500 mg	Every 8 hours	14 days

DS, double strength; SS, single strength.
[a]Dosing intervals for normal renal function.

incidence of resistant *E. coli*. For most adult females, short-course therapy is the treatment of choice for uncomplicated lower UTIs. Short-course therapy is inappropriate for patients who have had previous infections caused by resistant bacteria, for male patients, and for patients with complicated UTIs. If symptoms recur or do not respond to therapy, a urine culture should be obtained and conventional therapy with a suitable agent instituted.[1]

SYMPTOMATIC ABACTERIURIA

Symptomatic abacteriuria or acute urethral syndrome represents a clinical syndrome in which females present with dysuria and pyuria, but the urine culture reveals less than 10^5 bacteria/mL of urine. Acute urethral syndrome accounts for more than half the complaints of dysuria seen in the community today. These women

TABLE 125-5 Evidence-Based Empirical Treatment of Urinary Tract Infections and Prostatitis

Diagnosis	Pathogens	Treatment Recommendation	Comments
Acute uncomplicated cystitis	*Escherichia coli* *Staphylococcus saprophyticus*	1. Trimethoprim-sulfamethoxazole × 3 days (A, I)[a] 2. Fluoroquinolone × 3 days (A, II)[a] 3. Nitrofurantion × 5 days (B, I)[a] 4. β-lactams × 3 days (E, III)[a]	Short-course therapy more effective than single dose β-Lactams as a group are not as effective in acute cystitis then trimethoprim-sulfamethoxazole or the fluoroquinolones[a]
Pregnancy	As above	1. Amoxicillin-clavulanate × 7 days 2. Cephalosporin × 7 days 3. Trimethoprim-sulfamethoxazole × 7 days	Avoid trimethoprim-sulfamethoxazole during third trimester
Acute pyelonephritis			
Uncomplicated	*E. coli*	1. Quinolone × 14 days (A, II)[a] 2. Trimethoprim-sulfamethoxazole (if susceptible) × 14 days (B, II)[a]	Can be managed as outpatient
	Gram-positive bacteria	1. Amoxicillin or amoxicillin-clavulanic acid × 14 days (B, III)[a]	
Complicated	*E. coli* *Proteus mirabilis* *Klebisella pneumoniae* *Pseudomonas aeruginosa* *Enterococcus faecalis*	1. Quinolone × 14 days (B, III)[a] 2. Extended-spectrum penicillin plus aminoglycoside (B, III)[a]	Severity of illness will determine duration of IV therapy; culture results should direct therapy Oral therapy may complete 14 days of therapy
Prostatitis	*E. coli* *K. pneumoniae* *Proteus* spp. *P. aeruginosa*	1. Trimethoprim-sulfamethoxazole × 4–6 weeks 2. Quinolone × 4–6 weeks	Acute prostatitis may require IV therapy initially Chronic prostatitis may require longer treatment periods or surgery

[a]Strength of recommendations: A, good evidence for; B, moderate evidence for; C, poor evidence for and against; D, moderate against; E, good evidence against. Quality of evidence: I, at least one proper randomized, controlled study; II, one well-designed clinical trial; III, evidence from opinions, clinical experience, and expert committees.
Data from Warren JW, Abrutyn E, Hebel JR, et al. Guidelines for antimicrobial treatment of uncomplicated acute bacterial cystitis and acute pyelonephritis. Clin Infect Dis 1999;29:745–758.

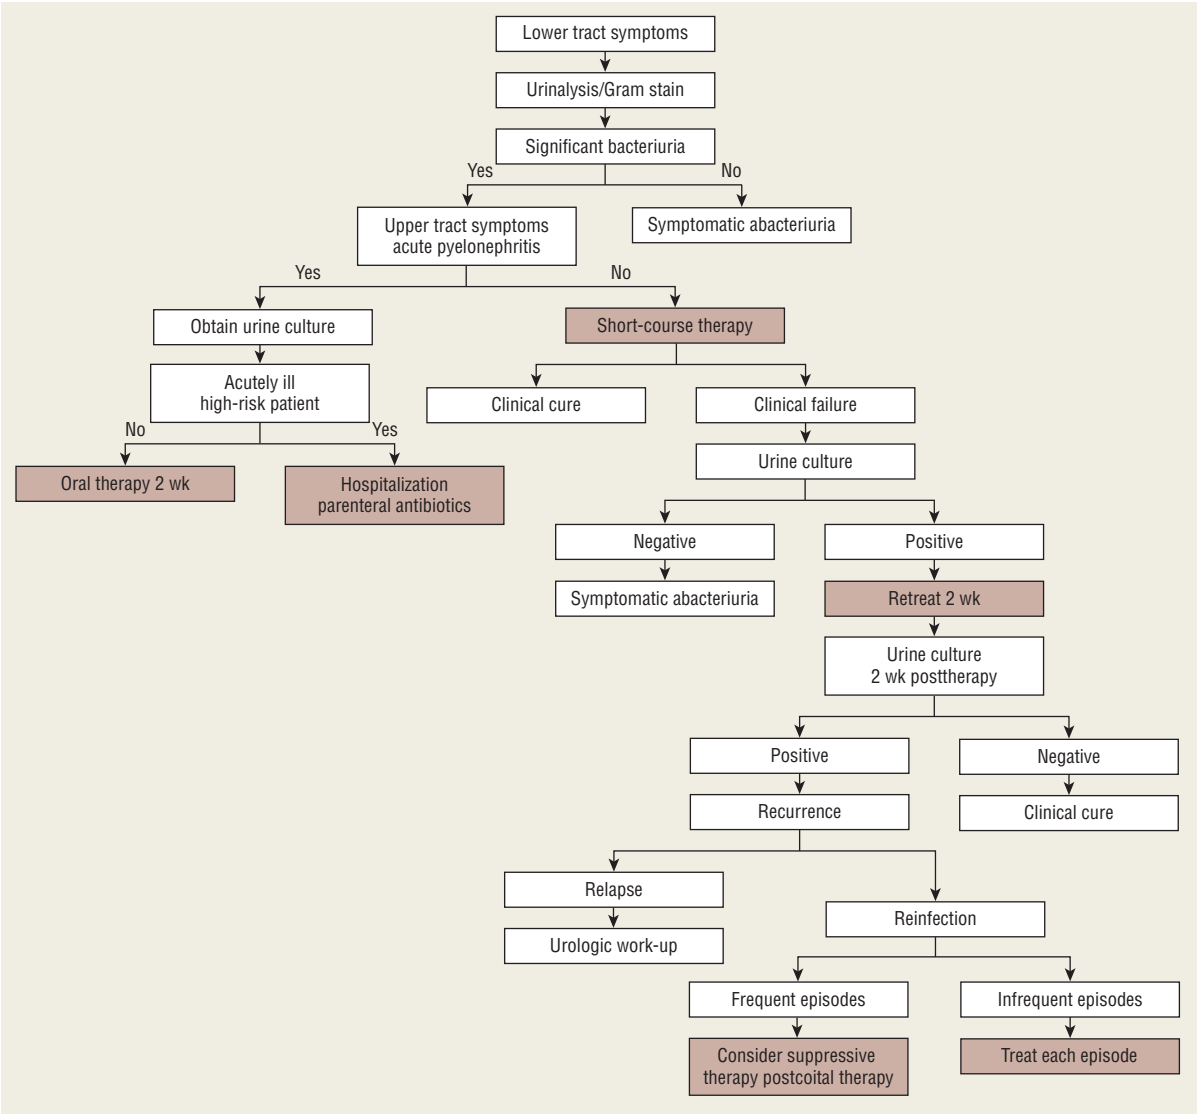

FIGURE 125-1. Management of UTIs in females.

most likely are infected with small numbers of coliform bacteria, including *E. coli, Staphylococcus* spp., or *Chlamydia trachomatis*. Additional causes include *Neisseria gonorrhoeae, Gardnerella vaginalis*, and *Ureaplasma urealyticum*.

Most patients presenting with pyuria will, in fact, have infection that requires treatment. Single-dose or short-course therapy with trimethoprim-sulfamethoxazole has been used effectively, and prolonged courses of therapy are not necessary for most patients. If single-dose or short-course therapy is ineffective, a culture should be obtained. If the patient reports recent sexual activity, therapy for *C. trachomatis* should be considered. Chlamydial treatment should consist of 1 g azithromycin or doxycycline 100 mg twice daily for 7 days. Often, concomitant treatment of all sexual partners is required to cure chlamydial infections and prevent reacquisition (see Chap. 126).

ASYMPTOMATIC BACTERIURIA

Asymptomatic bacteriuria is the finding of two consecutive urine cultures with $>10^5$ organisms/mL of the same organism in the absence of urinary symptoms. Most patients with asymptomatic bacteriuria are elderly and female. Pregnant women frequently present with asymptomatic bacteriuria. Although this group of patients typically responds to treatment, relapse and reinfection are very common, and chronic asymptomatic bacteriuria is difficult to eradicate.

The management of asymptomatic bacteriuria depends on the age of the patient and whether or not the patient is pregnant. In children, because of a greater risk of developing renal scarring and long-standing renal damage, treatment should consist of the same conventional courses of therapy as that used for symptomatic infection. The greatest risk of renal damage occurs during the first 5 years of life.[51] In nonpregnant females, therapy is controversial; however, treatment has little effect on the natural course of infections. Two groups characterize asymptomatic bacteriuria in the elderly: those with persistent bacteriuria and those with intermittent bacteriuria.

Several studies in hospitalized elderly subjects, however, have not found antimicrobial therapy to be efficacious for abacteruria.[52–55] A number of questions remains unanswered, for example: What is the effect of eradication of bacteriuria on life expectancy? What are the cost-effectiveness and risk-to-benefit ratio of therapy? What is the effect on morbidity? Certainly, with the information available and the high adverse reaction rate in the elderly, vigorous treatment and screening programs cannot be advocated.

COMPLICATED URINARY TRACT INFECTIONS

Acute Pyelonephritis

The presentation of high-grade fever (>38.3°C [100.9°F]) and severe flank pain should be treated as acute pyelonephritis, warranting aggressive management. Severely ill patients with pyelonephritis should be hospitalized and intravenous antimicrobials administered initially (see Table 125–5). However, milder cases may be managed with orally-administered antibiotics in an outpatient setting. Symptoms of nausea, vomiting, and dehydration may require hospitalization.

At the time of presentation, a Gram stain of the urine should be performed, along with a urinalysis, culture, and sensitivity tests. The Gram stain should indicate the morphology of the infecting organism(s) and help to direct the selection of an appropriate antibiotic. However, the precise identity and susceptibility of the infecting organism(s) will be unknown initially, warranting empirical therapy. The goals of treatment include the achievement of therapeutic concentrations of an antimicrobial agent in the bloodstream and urinary tract to which the invading organism is susceptible and sufficient therapy to eradicate residual infection in the tissues of the urinary tract.

In the mildly to moderately symptomatic patient in whom oral therapy is considered, an effective agent should be administered for at least a 2-week period, although use of highly active agents for 7 to 10 days may be sufficient.[1,56–60] Oral antibiotics that are highly active against the probable pathogens and that are sufficiently bioavailable are preferred. Although the sulfonamides and ampicillin or amoxicillin have been the primary choices for the treatment of gram-negative bacillary infections, they are no longer considered reliable agents for UTIs;[40,61] reports of increasing resistance to *E. coli* have tempered their use. In addition, treatment with trimethoprim-sulfamethoxazole (one double-strength tablet twice daily) for 2 weeks was superior to ampicillin, despite the organism being susceptible to both agents.[1,59,61] Agents such as trimethoprim-sulfamethoxazole and the fluoroquinolones are the agents of choice. If a Gram stain reveals gram-positive cocci, *Enterococcus faecalis* should be considered and treatment directed against this potential pathogen (ampicillin). Close followup of outpatient treatment is mandatory to ensure success.

In the seriously ill patient, parenteral therapy should be administered initially. Therapy should provide a broad spectrum of coverage and should be directed toward bacteremia or sepsis, if present. A number of antibiotic regimens have been used as empirical therapy, including an intravenous fluoroquinolone, an aminoglycoside with or without ampicillin, and extended-spectrum cephalosporins with or without an aminoglycoside.[1,62] Other options include aztreonam, the β-lactamase inhibitor combinations (e.g., ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam), carbapenems (e.g., imipenem, meropenem, doripenem or ertapenem), or intravenous trimethoprim-sulfamethoxazole.[63] If the patient has been hospitalized within the past 6 months, has a urinary catheter, or is a nursing home resident, the possibility of *P. aeruginosa* and enterococci, as well as multiple resistant organisms, should be considered. In this setting, ceftazidime, ticarcillin-clavulanate, piperacillin, aztreonam, meropenem, or imipenem in combination with an aminoglycoside is recommended. Ertapenem should not be used in this case owing to its inactivity against enterococci and *P. aeruginosa*.[62] The rationale for combination therapy is that in experimental animals, 3 days of aminoglycoside combination therapy followed by nonaminoglycoside single-agent therapy for 7 days resulted in a 100% cure rate.[56,61] If the patient responds to initial combination therapy, the aminoglycoside may be discontinued after 3 days. Although the aminoglycoside therapy is stopped, renal tissue concentrations of the aminoglycoside will persist for days. Based on antimicrobial sensitivity data, the patient then can be maintained or switched to a less expensive single agent, and ultimately, an appropriate oral agent may be used.

Effective therapy should stabilize the patient within 12 to 24 hours. A significant reduction in urine bacterial concentrations should occur in 48 hours. If bacteriologic response has not occurred, an alternative agent should be considered based on susceptibility testing. If the patient fails to respond clinically within 3 to 4 days or has persistently positive blood or urine cultures, further investigation is needed to exclude bacterial resistance, possible obstruction, papillary necrosis, intrarenal or perinephric abscess, or some other disease process. Usually by the third day of therapy the patient is afebrile and significantly less symptomatic. In general, after the patient has been afebrile for 24 hours, parenteral therapy may be discontinued, and oral therapy instituted to complete a 2-week course. Followup urine cultures should be obtained 2 weeks after completion of therapy to ensure a satisfactory response and detect possible relapse.

Urinary Tract Infections in Males

The management of UTIs in males is distinctly different and often more difficult than in females. Infections in male patients are considered to be complicated because endogenous bacteria in the presence of functional or structural abnormalities that disrupt the normal defense mechanisms of the urinary tract cause them. The incidence of infections in males younger than 60 years of age is much less than the incidence in females. During the adult years, the occurrence of infection can be related directly to some manipulation of the urinary tract. The most common causes are instrumentation of the urinary tract, catheterization, and renal and urinary stones. Uncomplicated infections are rare, but they may occur in young males as a result of homosexual activity, noncircumcision, and having sex with partners who are colonized with uropathogenic bacteria. As the patient ages, the most common cause of infection is related to bladder outlet obstruction because of prostatic hypertrophy. In addition, the prostate gland may become infected and provide a nidus for recurrent infection in males.

The conventional view is that therapy in males requires prolonged treatment (Fig. 125–2). A urine culture should be obtained before treatment because the cause of infection in men is not as predictable as in women. Single-dose or short-course therapy is not recommended in males. Considerably fewer data are available comparing various antimicrobial agents in males as compared with females. If gram-negative bacteria are presumed, trimethoprim-sulfamethoxazole or the quinolone antimicrobials should be considered because these agents achieve high renal tissue, urine, and prostatic concentrations.[15]

Initial therapy should be for 10 to 14 days. Factors associated with treatment success are isolation of a single organism, the absence of significant obstruction or anatomic abnormalities, a normally functioning urinary tract, and the absence of prostatic involvement. Parenteral therapy may be required in certain situations, such as in severely ill patients, in the presence of acute prostatitis or epididymitis, and in patients who cannot tolerate oral medications. A comparison of 2-week vs. 6-week therapy in males with recurrent infections who were given trimethoprim-sulfamethoxazole had cure rates of 29% and 62%, respectively.[64] Other investigators advocate longer treatment periods in males as well.[65] Followup cultures at 4 to 6 weeks after treatment are important in males to ensure bacteriologic cure. Many patients

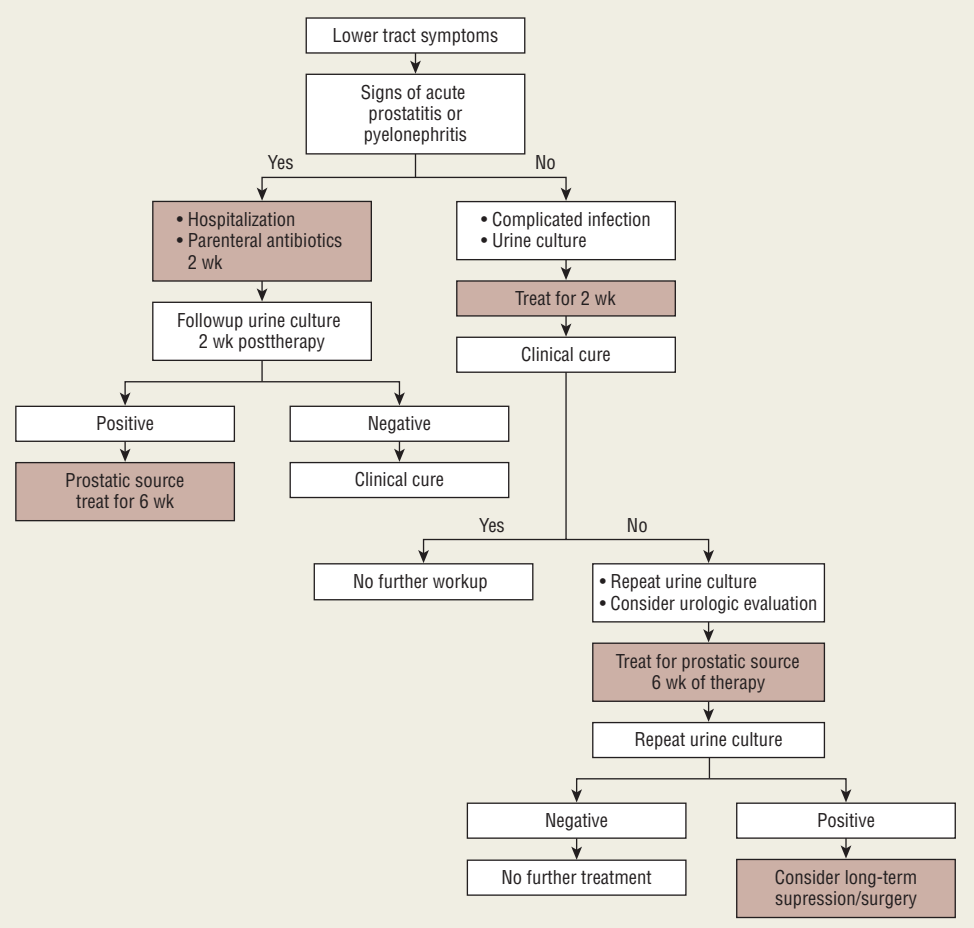

FIGURE 125-2. Management of UTIs in male.

require longer periods of treatment and possible alterations in antibiotics, depending on culture and sensitivity results and clinical response.

Recurrent Infections

Recurrent episodes of UTI account for a significant portion of all UTIs. Of the patients suffering from recurrent infections, 80% can be considered reinfections, that is, the recurrence of infection by an organism different from the organism isolated from the preceding infection. These patients most commonly are female, and recurrence develops in approximately 20% of females with cystitis. Reinfections can be divided into two groups: those with less than three episodes per year and those who develop more frequent infections.

Management strategies depend on predisposing factors, number of episodes per year, and the patient's preference. Factors commonly associated with recurrent infections include sexual intercourse and diaphragm or spermicide use for birth control. Therapeutic options include self-administered therapy, postcoital therapy, and continuous low-dose prophylaxis. In patients with infrequent infections (less than 3 infections per year), each episode may be treated as a separately occurring infection. Short-course therapy is appropriate in this setting. Many women have been treated successfully with self-administered short-course therapy at the onset of symptoms.[66]

In patients with more frequent symptomatic infections and no apparent precipitating event, long-term prophylactic antimicrobial therapy may be instituted. Prophylactic therapy reduces the frequency of symptomatic infections in elderly men, women, and children. In women, most studies show a reinfection rate of 2 to 3 per patient-year reduced to 0.1 to 0.2 per patient-year with treatment.[67] Before prophylaxis is initiated, patients should be treated conventionally with an appropriate agent. Trimethoprim-sulfa-methoxazole (one-half of a single-strength tablet), trimethoprim (100 mg daily), a fluoroquinolone (levofloxacin 500 mg daily) and nitrofurantoin (50 or 100 mg daily) all reduce the rate of reinfection as single-agent therapy.[67] Full-dose therapy with these agents is unnecessary, and single daily doses can be used. Therapy generally is prescribed for a period of 6 months, during which time urine cultures are followed monthly. If symptomatic episodes develop, the patient should receive a full course of therapy with an effective agent and should be restarted on prophylactic therapy.

In women who experience symptomatic reinfections in association with sexual activity, voiding after intercourse may help to prevent infection. Also, single-dose prophylactic therapy with trimethoprim-sulfamethoxazole taken after intercourse reduces the incidence of recurrent infection significantly.[68]

In postmenopausal women with recurrent infections, the lack of estrogen results in changes in the bacterial flora of the vagina, resulting in increased colonization with uropathogenic *E. coli*. Topically administered estrogen cream reduces the incidence of infections in this population.[18,19]

The remaining 20% of recurrent UTIs are relapses, that is, persistence of infection with the same organism after therapy for an isolated UTI. The recurrence of symptomatic or asymptomatic bacteriuria after therapy usually indicates that the patient has renal involvement, a structural abnormality of the urinary tract, or chronic bacterial prostatitis. In the absence of structural abnormalities, relapse often is related to renal infection and requires a long duration of treatment. Women who relapse after short-course therapy should receive a 2-week course of therapy. In patients who

relapse after 2 weeks of therapy, therapy should be continued for another 2 to 4 weeks. If relapse occurs after 6 weeks of therapy, urologic evaluation should be performed, and any obstructive lesion should be corrected. If this is not possible, therapy for 6 months or longer may be considered. Asymptomatic adults who have no evidence of urinary obstruction should not receive long-term therapy.

In males, relapse usually indicates bacterial prostatitis, the most common cause of persistent bacteriuria. Although many agents have been used for long-term therapy of relapses, trimethoprim-sulfamethoxazole and the fluoroquinolones appear to be highly effective.

SPECIAL CONDITIONS

UTIs in Pregnancy

During pregnancy, significant physiologic changes occur to the entire urinary tract that dramatically alter the prevalence of UTIs and pyelonephritis. Severe dilation of the renal pelvis and ureters, decreased ureteral peristalsis, and reduced bladder tone occur during pregnancy.[69] These changes result in urinary stasis and reduced defenses against reflux of bacteria to the kidneys. In addition, increased urine content of amino acids, vitamins, and nutrients encourages bacterial growth. All of these factors increase the incidence of bacteriuria, resulting in symptomatic infections, especially during the third trimester.

Asymptomatic bacteriuria occurs in 4% to 7% of pregnant patients. Of these, 20% to 40% will develop acute symptomatic pyelonephritis during pregnancy. If untreated, asymptomatic bacteriuria has the potential to cause significant adverse effects, including prematurity, low birth weight, and stillbirth.[70,71] Because pyelonephritis is associated with significant adverse events during pregnancy, routine screening tests for bacteriuria should be performed at the initial prenatal visit and again at 28 weeks' gestation. In patients with significant bacteriuria, symptomatic or asymptomatic, treatment is recommended so as to avoid possible complications. Organisms associated with bacteriuria are the same as those seen in uncomplicated UTIs, with *E. coli* isolated most frequently.

Therapy should consist of an agent administered for 7 days that has a relatively low adverse-effect potential and is safe for the mother and baby. The administration of amoxicillin, amoxicillin-clavulanate, or cephalexin, is effective in 70% to 80% of patients. Nitrofurantoin has been utilized in pregnancy, however must be used with caution as occurrences of birth defects have been reported. Tetracyclines should be avoided because of teratogenic effects, and sulfonamides should not be administered during the third trimester because of the possible development of kernicterus and hyperbilirubinemia. In addition, the available fluoroquinolones should not be given because of their potential to inhibit cartilage and bone development in the newborn. A follow-up urine culture 1 to 2 weeks after completing therapy and then monthly until gestation is complete is recommended.

Catheterized Patients

The use of an indwelling catheter frequently is associated with infection of the urinary tract and represents the most common cause of hospital-acquired infection. The incidence of catheter-associated infection is related to a variety of factors, including method and duration of catheterization, the catheter system (open or closed), the care of the system, the susceptibility of the patient, and the technique of the healthcare personnel inserting the catheter. Catheter-related infections are reasonably preventable infections, and are now considered one of the hospital-acquired complications chosen by the Centers for Medicare and Medicaid Services (CMS) in which hospitals will no longer receive reimbursement for treatment. [72,73]

Bacteria may enter the bladder in a number of ways. During the catheterization, bacteria may be introduced directly into the bladder from the urethra. Once the catheter is in place, bacteria may pass up the lumen of the catheter via the movement of air bubbles, by motility of the bacteria, or by capillary action. In addition, bacteria may reach the bladder from around the exudative sheath that surrounds the catheter in the urethra. Cleaning the periurethral area thoroughly and applying an antiseptic (povidone-iodine) can minimize infection occurring during insertion of the catheter. The use of closed drainage systems has reduced significantly the ability of bacteria to pass up the lumen of the catheter and cause infection. A bacterium passing around the catheter sheath in the urethra is probably the most important pathway for infection. Avoiding manipulation of the catheter and trauma to the urethra and urethral meatus can minimize this path of acquisition.

Patients with indwelling catheters acquire UTIs at a rate of 5% per day.[72–74] The closed systems are capable of preventing bacteriuria in most patients for up to 10 days with appropriate care. After 30 days of catheterization, however, there is a 78% to 95% incidence of bacteriuria despite use of a closed system.[73,75] Unfortunately, UTI symptoms in catheterized patient are not clearly defined. Fever, peripheral leukocytosis, and urinary signs and symptoms may be of little predictive value.[72,73] When bacteriuria occurs in the asymptomatic, short-term catheterized patient (<30 days), the use of systemic antibiotics should be withheld and the catheter removed as soon as possible. If the patient becomes symptomatic, the catheter should be removed and treatment as described for complicated infections started. The optimal duration of therapy is unknown. In the long-term catheterized patient (>30 days), bacteriuria is inevitable.[72,73] The administration of systemic antibiotics active against the infecting organism will sterilize the urine; however, reinfection occurs rapidly in more than 50% of patients. In addition, resistant organisms recolonize the urine. Symptomatic patients must be treated because they are at risk of developing pyelonephritis and bacteremia. Bacteria adhere to the catheter and produce a biofilm consisting of bacterial glycocalyces, Tamm-Horsfall protein, as well as apatite and struvite salts, that act to protect the bacteria from antibiotics.[74] Recatheterization with a new, sterile unit should be performed in those symptomatic patients if the existing catheter has been in place for more than 2 weeks.

Various methods have been proposed to prevent the development of bacteriuria and infection in the patient with an indwelling catheter (see Table 125–5). The success of these methods depends on the type of catheter and the length of time it is in place. The use of constant bladder irrigation with antiseptic or antibacterial solutions reduces the incidence of infection in those with open drainage systems, but this approach has no advantage in those with closed systems. The use of prophylactic systemic antibiotics in patients with short-term catheterization reduces the incidence of infection over the first 4 to 7 days.[73,75] In long-term catheterized patients, however, antibiotics only postpone the development of bacteriuria and lead to the emergence of resistant organisms.

PROSTATITIS

Bacterial prostatitis is an inflammation of the prostate gland and surrounding tissue as a result of infection. It is classified as either acute or chronic. By definition, pathogenic bacteria and significant inflammatory cells must be present in prostatic secretions and urine to make the diagnosis of bacterial prostatitis. Prostatitis occurs

rarely in young males, but it is commonly associated with recurrent infections in persons older than 30 years of age. As many as 50% of all males develop some form of prostatitis at some period in their life.[76–78] The acute form typically is an acute infectious disease characterized by a sudden onset of fever, tenderness, and urinary and constitutional symptoms. Chronic prostatitis presents with few symptoms related to the prostate but rather symptoms of urinating difficulty, low back pain, perineal pressure, or a combination of these. It represents a recurring infection with the same organism that results from incomplete eradication of bacteria from the prostate gland.

PATHOGENESIS AND ETIOLOGY

The exact mechanism of bacterial infection of the prostate is not well understood. The possible routes of infection are the same as those for UTIs. Reflux of infected urine into the prostate gland is thought to play an important role in causing infection. Intraprostatic reflux of urine occurs commonly and results in direct inoculation of infected urine into the prostate.[76–78] In addition, intraprostatic reflux of sterile urine can result in a chemical prostatitis and may be the cause of nonbacterial prostatitis. Sexual intercourse may contribute to infection of the prostate gland because prostatic secretions from men with chronic prostatitis and vaginal cultures from their sexual partners grow identical organisms. Other known causes of bacterial prostatitis include indwelling urethral and condom catheterization, urethral instrumentation, and transurethral prostatectomy in patients with infected urine.

A number of physiologic factors are believed to contribute to the development of prostatitis. Functional abnormalities found in bacterial prostatitis include altered prostate secretory functions. Prostatic fluid obtained from normal males contains prostatic antibacterial factor. This heat-stable, low-molecular-weight cation is a zinc-complexed polypeptide that is bactericidal to most urinary tract pathogens.[79] The antibacterial activity of prostatic antibacterial factor is related directly to the zinc content of prostatic fluid. Prostate fluid zinc levels and prostatic antibacterial factor activity also appear diminished in patients with prostatitis, as well as in the elderly.[79] Whether these changes are a cause or effect of prostatitis remains to be determined.

The pH of prostatic secretions in patients with prostatitis is altered.[80] Normal prostatic secretions have a pH in the range of 6.6 to 7.6. With increasing age, the pH tends to become more alkaline. In patients with inflammation of the prostate, prostatic secretions may have an alkaline pH in the range of 7 to 9. These changes suggest a generalized secretory dysfunction of the prostate that not only can affect the pathogenesis of prostatitis but also can influence the mode of therapy.

Gram-negative enteric organisms are the most frequent pathogens in acute bacterial prostatitis.[76–78] *E. coli* is the predominant organism, occurring in 75% of cases. Other gram-negative organisms frequently isolated include *K. pneumoniae, P. mirabilis*, and less frequently, *P. aeruginosa, Enterobacter* spp., and *Serratia* spp. Occasionally, cases of gonococcal and staphylococcal prostatitis occur, but they are infrequent.

E. coli most commonly causes chronic bacterial prostatitis, with other gram-negative organisms isolated less frequently. The importance of gram-positive organisms in chronic bacterial prostatitis remains controversial. *S. epidermidis, S. aureus*, and diphtheroids have been isolated in some studies.

CLINICAL PRESENTATION

Acute bacterial prostatitis presents as other acute infections (Table 125–6). Massage of the prostate will express a purulent discharge that will readily grow the pathogenic organism. Prostatic massage is contraindicated in acute bacterial prostatitis, however, because of the risk of inducing bacteremia and associated local pain. The diagnosis of acute bacterial prostatitis can be made from the patient's clinical presentation and the presence of significant bacteriuria. As with other UTIs, the infecting organism can be isolated from a midstream specimen.

TABLE 125-6 Clinical Presentation of Bacterial Prostatitis

Signs and symptoms
Acute bacterial prostatitis: high fever, chills, malaise, myalgia, localized pain (perineal, rectal, sacrococcygeal), frequency, urgency, dysuria, nocturia, and retention
Chronic bacterial prostatitis: voiding difficulties (frequency, urgency, dysuria), low back pain, and perineal and suprapubic discomfort
Physical examination
Acute bacterial prostatitis: swollen, tender, tense, or indurated gland
Chronic bacterial prostatitis: boggy, indurated (enlarged) prostate in most patients
Laboratory tests
Bacteriuria
Bacteria in expressed prostatic secretions

In contrast, chronic bacterial prostatitis is more difficult to diagnose and treat. Chronic bacterial prostatitis typically is characterized by recurrent UTIs with the same pathogen and is the most common cause of recurrent UTI in males. The patient's clinical presentation can vary widely (see Table 125–6). Many adults, however, are asymptomatic.

Because physical examination of the prostate is often normal, urinary tract localization studies are critical to the diagnosis of chronic bacterial prostatitis. The method of quantitative localization culture, as described by Meares and Stamey,[81] remains the diagnostic standard (Fig. 125–3). The method compares the bacterial growth in sequential urine and prostatic fluid cultures obtained during micturition. The first 10 mL of voided urine is collected (voiding bladder 1, or VB_1) and constitutes urethral urine. After approximately 200 mL of urine has been voided, a 10-mL midstream sample is collected (VB_2). This specimen represents bladder urine. After the patient voids, the prostate is massaged, and expressed prostatic secretions (EPS) are collected. After prostatic massage, the patient voids again, and 10 mL of urine is collected (VB_3).

The diagnosis of bacterial prostatitis is made when the number of bacteria in EPS is 10 times that of the urethral sample (VB_1) and midstream sample (VB_2). If no EPS is available, the urine sample following massage (VB_3) should contain a bacterial count 10-fold greater than that of VB_1 or VB_2. If significant bacteriuria is present, ampicillin,

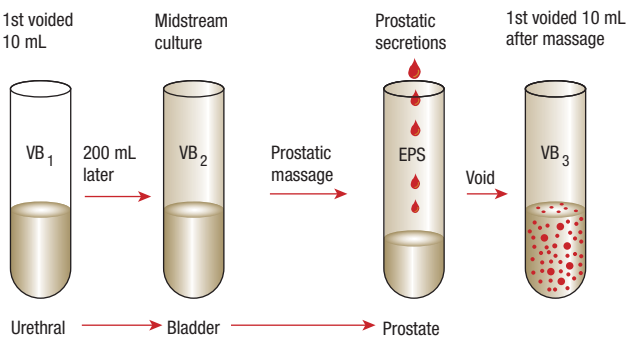

FIGURE 125-3. Segmented cultures of the lower tract in men. (EPS, expressed prostatic secretions; VB_1, voiding bladder 1; VB_2, voiding bladder 2; VB_3, voiding bladder 3.)

cephalexin, or nitrofurantoin should be given for 2 to 3 days to sterilize the urine prior to performing the localization study.

TREATMENT

9 The goals in the management of bacterial prostatitis are, in general, the same as those for UTIs. Acute bacterial prostatitis responds well to appropriate antimicrobial therapy that is directed at the most commonly isolated organisms. Prostatic penetration of antimicrobials occurs because the acute inflammatory reaction alters the cellular membrane barrier between the bloodstream and the prostate. Most patients can be managed with oral antimicrobial agents, such as trimethoprim-sulfamethoxazole and the fluoroquinolones (e.g., ciprofloxacin, levofloxacin) (see Table 125–5). Other effective agents in this setting include cephalosporins, and β-lactam–β-lactamase combinations. Although intravenous therapy is rarely necessary for total treatment, intravenous to oral sequential therapy with trimethoprim-sulfamethoxazole or the fluoroquinolones is appropriate. The conversion to an oral antibiotic can be considered after the patient is afebrile for 48 hours or after 3 to 5 days of intravenous therapy. The total course of antibiotic therapy should be 4 weeks in order to reduce the risk of development of chronic prostatitis. Therapy may be prolonged with chronic prostatitis (6 to 12 weeks). Long-term suppressive therapy also may be initiated for recurrent infections, such as three times weekly ciprofloxacin, trimethoprim-sulfamethoxazole regular-strength tablet daily, or nitrofurantoin 100 mg daily.[81]

Chronic bacterial prostatitis often presents a more vexing situation because cures are obtained rarely. Despite high serum concentrations of antibacterial drugs in excess of the minimal inhibitory concentrations of the infecting organisms, bacteria persist in prostatic fluid. Most likely the failure to eradicate sensitive bacteria is caused by the inability of antibiotics to reach sufficient concentrations in the prostatic fluid and cross the prostatic epithelium.

Several factors that determine antibiotic diffusion into prostatic secretions were delineated from the canine model. Lipid solubility is a major determinant in the ability of drugs to diffuse from plasma across epithelial membranes. The degree of ionization in plasma also affects the diffusion of drugs. Only unionized molecules can cross the lipid barrier of prostatic cells, and the drug's pK_a (negative logarithm of acid ionization constant) directly determines the fraction of unchanged drug.

The pH gradient across the membrane has an influence on tissue penetration as well. A pH gradient of at least 1 pH unit between separate compartments allows for ion trapping. As the unionized drug crosses the epithelial barrier into prostatic fluid, it becomes ionized, allowing less drug to diffuse back across the lipid barrier. In early studies with the canine model, the prostatic pH was reported to be acidic (6.4).[80] In humans, however, the pH of prostatic secretions from an inflamed prostate is actually basic (8.1 to 8.3).[80]

The choice of antibiotics in chronic bacterial prostatitis should include agents that are capable of reaching therapeutic concentrations in the prostatic fluid and which possess the spectrum of activity to be effective. Agents that achieve therapeutic prostatic concentrations include trimethoprim and the fluoroquinolones. Sulfamethoxazole penetrates poorly and probably contributes very little to trimethoprim. The fluoroquinolones appear to provide the best therapeutic options in the management of chronic bacterial prostatitis. Trimethoprim-sulfamethoxazole is also effective. Therapy should be continued for 4 to 6 weeks initially. Longer treatment periods may be necessary in some cases. If therapy fails with these regimens, chronic suppressive therapy may be used or surgery considered.

PHARMACOECONOMIC CONSIDERATIONS

The cost-effective management of UTIs requires knowledge of its pathogenesis and causative organisms associated with the various clinical syndromes described in this chapter. The costs associated with managing a UTI include direct costs, such as laboratory tests, medication, and healthcare visits. The indirect costs include lost work time and general quality-of-life issues such as disease or therapy adverse effects.

Direct costs are those associated with diagnosis, treatment, and followup. The cost of pharmaceuticals varies according to the agents used and the duration of therapy. Trimethoprim-sulfamethoxazole and ampicillin are rather inexpensive; however with rates of resistance, the risk of therapy failure is high, leading to increased costs. The fluoroquinolones also are highly effective agents but generally are more expensive, and a rise in their utilization is now being associated with increasing resistance.[61,82] In general, the outcome and total cost depend on whether therapy is empirical or definitive (based on a culture diagnosis for acute infection), and if the individual patient is compliant with the regimen.

ABBREVIATIONS

CFU: colony forming unit

EPS: expressed prostatic secretions

PMN: polymorphonuclear leukocyte

UTI: urinary tract infection

WBC: white blood cell

CHAPTER 126

Sexually Transmitted Diseases

LEROY C. KNODEL

KEY CONCEPTS

1. All recommended treatment regimens for gonorrhea include antibiotic therapy directed against *Chlamydia* species because of the high prevalence of coexisting infections, unless chlamydia has been ruled out.
2. Parenteral penicillin is the treatment of choice for all syphilis infections. For patients who are penicillin allergic, few well-studied alternative agents are available, and all are oral medications that require 2 to 4 weeks of therapy to be effective. Patient compliance and thus efficacy are a concern when alternative regimens must be used.
3. Chlamydia genital tract infections represent the most frequently reported communicable disease in the United States. In females, these infections are frequently asymptomatic or minimally symptomatic and, if left untreated, are associated with the development of pelvic inflammatory disease and attendant complications such as ectopic pregnancy and infertility. As a result, all sexually active females aged 20 to 25 years and sexually active women with multiple sexual partners should be screened annually for this infection.
4. Oral acyclovir, famciclovir, and valacyclovir are effective in reducing viral shedding, duration of symptoms, and time to healing of first-episode genital herpes infections, with maximal benefits seen when therapy is initiated at the earliest stages of infection. The benefit of these agents for recurrent infections has not been demonstrated. Patient-initiated, single-day antiviral therapy started within 6 to 12 hours of prodromal symptom onset offers an alternative to continuous suppressive therapy of recurrent infection in some individuals.
5. Metronidazole and tinidazole are the only agents currently approved in the United States to treat trichomoniasis. Although a single 2-g dose of either agent is widely used for compliance and other reasons, the alternative 7-day metronidazole regimen may be a better choice if sexual partners of treated individuals cannot be treated concurrently.

The spectrum of sexually transmitted diseases (STDs) has broadened from the classic venereal diseases—gonorrhea, syphilis, chancroid, lymphogranuloma venereum, and granuloma inguinale—to include a variety of pathogens known to be spread by sexual contact (Table 126–1). Because of the large number of infected individuals, the diversity of clinical manifestations, the changing drug-susceptibility patterns of some pathogens, and the high frequency of multiple STDs occurring simultaneously in infected individuals, the diagnosis and management of patients with STDs are much more complex today than they were even a decade ago.[1–4]

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Despite a higher reported incidence of most major STDs in men, the complications of STDs generally are more frequent and severe in women. In particular, serious effects on maternal and infant health during pregnancy are well documented.[1,4] Damage to reproductive organs, increased risk of cancer, complications associated with pregnancy, and transmission of disease to the fetus or newborn are associated with several STDs. As a result of the physiologic, psychosocial, and economic consequences of STDs, and because of the increasing prevalence of some viral STDs, such as human immunodeficiency virus (HIV) and genital herpes, for which curative therapy is not available, there is continuing research into STDs and the primary prevention of these diseases.[2–5]

With the exception of HIV infection, which is reviewed in detail in Chapter 134, the most frequently occurring STDs in the United States are discussed in this chapter. For other less common STDs, only recommended treatment regimens are presented. The most current information on the epidemiology, diagnosis, and treatment of STDs provided by the U.S. Centers for Disease Control and Prevention (CDC) can be obtained at the CDC Website (*www.cdc.gov*).

Numerous interrelated factors contribute to the epidemic nature of STDs. Sociocultural, demographic, and economic factors, together with patterns of sexual behavior, host susceptibility to infection, changing properties of the causative pathogens, disease transmission by asymptomatic individuals, and environmental factors, are important determinants of the frequency and distribution of STDs in the United States and worldwide.

Age is one of the most important demographic determinants of STD incidence. Two thirds of STD cases each year occur in persons in their teens and twenties, the peak years of sexual activity. With increasing age, the incidence of most STDs decreases exponentially. In sexually active teenagers, STD rates are highest in the youngest, suggesting that physiologic differences may contribute to increased susceptibility.[2–5]

Age-specific rates of STDs are higher in men than in women; however, reported rates may not represent true gender differences but rather may reflect greater ease of detection in men. In recent years, the ratio of male-to-female cases for most STDs has declined, possibly reflecting improvements in the diagnosis of STDs in asymptomatic women or changes in female sexual behavior following the availability of improved methods of contraception. Although some racial disparity exists for rates of STD infection, it is possible that this is a reflection of socioeconomic differences.[1–5]

TABLE 126-1 Sexually Transmitted Diseases

Disease	Associated Pathogens
Bacterial	
Gonorrhea	*Neisseria gonorrhoeae*
Syphilis	*Treponema pallidum*
Chancroid	*Haemophilus ducreyi*
Granuloma inguinale	*Calymmatobacterium granulomatis*
Enteric disease	*Salmonella* spp, *Shigella* spp, *Campylobacter* fetus
Campylobacter infection	*Campylobacter jejuni*
Bacterial vaginosis	*Gardnerella vaginalis, Mycoplasma hominis, Bacteroides* spp, *Mobiluncus* spp
Group B streptococcal infections	Group B *Streptococcus*
Chlamydial	
Nongonococcal urethritis	*Chlamydia trachomatis*
Lymphogranuloma venereum	*Chlamydia trachomatis,* type L
Viral	
Acquired immunodeficiency syndrome	Human immunodeficiency virus
Herpes genitalis	Herpes simplex virus, types I and II
Viral hepatitis	Hepatitis A, B, C, and D viruses
Condylomata acuminata	Human papillomavirus
Molluscum contagiosum	Poxvirus
Cytomegalovirus infection	Cytomegalovirus
Mycoplasmal	
Nongonococcal urethritis	*Ureaplasma urealyticum*
Protozoal	
Trichomoniasis	*Trichomonas vaginalis*
Amebiasis	*Entamoeba histolytica*
Giardiasis	*Giardia lamblia*
Fungal	
Vaginal candidiasis	*Candida albicans*
Parasitic	
Scabies	*Sarcoptes scabiei*
Pediculosis pubis	*Phthirus pubis*
Enterobiasis	*Enterobius vermicularis*

The single greatest risk factor for contracting STDs is the number of sexual partners. As the number of sexual partners increases, the risk of being exposed to someone infected with an STD increases. Sexual preference also plays a major role in the transmission of STDs. For all major STDs, rates are disproportionately greater in men who have sex with men (MSM) than in heterosexuals. Also, a number of less common STDs, including several caused by enteric protozoans and bacterial pathogens, occur primarily in MSM. The major risk factors for MSM appear to be related to the greater number of sexual partners and the practice of unprotected anal-genital, oral-genital, and oral-anal intercourse. In addition, prostitution and illicit drug use are associated with a higher incidence of most STDs.[1–5]

Some of the most serious sequelae of STDs are associated with congenital or perinatal infections. Most neonatal infections are acquired at birth, after infant passage through an infected cervix or vagina. Neonatal *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and herpes simplex virus (HSV) infections are associated with this type of spread. For pregnant women with syphilis, infection is usually transmitted transplacentally, producing a congenital infection. Depending on the organism, neonatal infections can manifest in a variety of ways, produce significant morbidity, and in some cases result in infant death.[1–4]

Other than complete abstinence, the most effective way to prevent STD transmission is by maintaining a mutually monogamous sexual relationship between uninfected partners. Short of this, use of barrier contraceptive methods, such as the male and female condoms, diaphragm, cervical cap, vaginal sponges, and vaginal spermicides alone or in combination, provides varying degrees of protection from a number of STDs. When used correctly and consistently, male latex condoms with or without spermicide are more effective than natural skin condoms in protecting against STD transmission, including HIV, gonorrhea, chlamydia, trichomoniasis, HSV, and human papillomavirus (HPV). When lubrication is desired with latex condoms, water-based products, such as K-Y jelly, are recommended because oil-based agents (e.g., petroleum jelly) can weaken latex condoms and reduce their effectiveness. For latex-allergic individuals, other synthetic condoms (e.g., polyurethane) appear to possess efficacy against STD transmission similar to latex condoms. The female condom is a lubricated polyurethane sheath with a diaphragm-like ring on each end that can be used as a protective device for women with male sexual partners who do not desire to use a condom. Limited data suggest that the female condom blocks penetration of viruses, including HIV; for nonviral STDs, the female condom provides STD protection similar to the male condom.[1,3,5,6] At one time, use of nonoxynol-9, a vaginal spermicide with cytolytic activity, was advocated to reduce the transmissibility of several STDs. This was based in large part on in vitro and animal data. However, nonoxynol-9 does not reduce the risk of transmission of common STDs and actually can increase the risk of HIV transmission. Frequent use of nonoxynol-9 damages vaginal, cervical, and rectal epithelium, leading to increased transmissibility of HIV and possibly other STDs. Diaphragms may protect against cervical gonorrheal, chlamydial, and trichomonal infections.[1,5–8]

The varied spectrum of clinical syndromes produced by common STDs is determined not only by the etiologic pathogen(s) but also by differences in male and female anatomy and reproductive physiology. For a number of STDs, the signs and symptoms overlap sufficiently to prevent accurate diagnosis without microbiologic confirmation. Frequently, symptoms are minimal or absent despite the presence of infection. Table 126–2 lists common clinical syndromes associated with STDs.[1–4]

GONORRHEA

EPIDEMIOLOGY AND ETIOLOGY

The gram-negative diplococcus *N. gonorrhoeae* is the causative organism of gonorrhea. Although the rate of reported cases in the United States has remained relatively stable over the last decade, over 300,000 cases were reported in 2008.[1,9] Of concern, however, are the substantial number of infections that remain undiagnosed and unreported.[1,9] Humans are the only known natural host of this intracellular parasite. Because of its rapid incubation period and the large number of infected individuals with asymptomatic disease, gonorrhea is difficult to control.[1,10–15]

Although the risk of a female acquiring a cervical infection after a single episode of vaginal intercourse with an infected male partner is high and increases with multiple exposures, the risk of transmission from an infected female to an uninfected male is not as great following a single act of coitus. No data are available on the risk of transmission after other types of sexual contact.[10–14]

PATHOPHYSIOLOGY

On contact with a mucosal surface lined by columnar, cuboidal, or noncornified squamous epithelial cells, the gonococci attach to cell membranes by means of surface pili and are then pinocytosed. The virulence of the organism is mediated primarily by the presence of pili and other outer membrane proteins. After mucosal damage is established, polymorphonuclear (PMN) leukocytes invade the tissue, submucosal abscesses form, and purulent exudates are secreted.[10–15]

TABLE 126-2 Selected Syndromes Associated with Common Sexually Transmitted Pathogens

Syndrome	Commonly Implicated Pathogens	Common Clinical Manifestations[a]
Urethritis	*Chlamydia trachomatis*, herpes simplex virus, *Neisseria gonorrhoeae*, *Trichomonas vaginalis*, *Ureaplasma urealyticum*	Urethral discharge, dysuria
Epididymitis	*C. trachomatis*, *N. gonorrhoeae*	Scrotal pain, inguinal pain, flank pain, urethral discharge
Cervicitis/vulvovaginitis	*C. trachomatis, Gardnerella vaginalis*, herpes simplex virus, human papillomavirus, *N. gonorrhoeae, T. vaginalis*	Abnormal vaginal discharge, vulvar itching/irritation, dysuria, dyspareunia
Genital ulcers (painful)	*Haemophilus ducreyi*, herpes simplex virus	Usually multiple vesicular/pustular (herpes) or papular/pustular (*H ducreyi*) lesions that can coalesce; painful, tender lymphadenopathy[b]
Genital ulcers (painless)	*Treponema pallidum*	Usually single papular lesion
Genital/anal warts	Human papillomavirus	Multiple lesions ranging in size from small papular warts to large exophytic condylomas
Pharyngitis	*C. trachomatis* (?), herpes simplex virus, *N. gonorrhoeae*	Symptoms of acute pharyngitis, cervical lymphadenopathy, fever[c]
Proctitis	*C. trachomatis*, herpes simplex virus, *N. gonorrhoeae, T. pallidum*	Constipation, anorectal discomfort, tenesmus, mucopurulent rectal discharge
Salpingitis	*C. trachomatis, N. gonorrhoeae*	Lower abdominal pain, purulent cervical or vaginal discharge, adnexal swelling, fever[d]

[a]For some syndromes, clinical manifestations can be minimal or absent.
[b]Recurrent herpes infection can manifest as a single lesion.
[c]Most cases of pharyngeal gonococcal infection are asymptomatic.
[d]Salpingitis increases the risk of subsequent ectopic pregnancy and infertility.

CLINICAL PRESENTATION

Individuals infected with gonorrhea can be symptomatic or asymptomatic, have complicated or uncomplicated infections, and have infections involving several anatomic sites. Interestingly, most of the symptomatic patients who are not treated become asymptomatic within 6 months, with only a few becoming asymptomatic carriers of the disease.[10–13] The most common clinical features of gonococcal infections are presented in Table 126–3.

Complications associated with untreated gonorrhea appear more pronounced in women, likely a result of a high percentage who experience signs and symptoms that are nonspecific and minimally symptomatic. As a result, many women do not seek treatment until after the development of serious complications, such as pelvic inflammatory disease (PID). Approximately 15% of women with gonorrhea develop PID. Left untreated, PID can be an indirect cause of infertility and ectopic pregnancies. In 0.5% to 3.0% of patients with gonorrhea, the gonococci invade the bloodstream and produce disseminated disease. Disseminated gonococcal infection (DGI) is 3 times more common in women than in men. The usual clinical manifestations of DGI are tender necrotic skin lesions, tenosynovitis, and monarticular arthritis.[1,10–14]

DIAGNOSIS

Diagnosis of gonococcal infections can be made by gram-stained smears, culture, or methods based on the detection of cellular components of the gonococcus (e.g., enzymes, antigens, DNA, or lipopolysaccharide) in clinical specimens. Various stains have been used to identify gonococci microscopically, with the Gram stain the most widely used in clinical practice. Gram-stained smears are positive for gonococci when gram-negative diplococci of typical kidney bean morphology are identified within PMN leukocytes.[1,10–14] In the presence of equivocal smears (extracellular gonococcal forms that can be nonpathogenic, commensal *Neisseria*, or gram-negative diplococci of atypical morphology), culture is mandatory. In urethral smears from men with symptomatic urethritis, the smear is highly sensitive and specific, and is considered diagnostic for infection. Because of their low sensitivity, gram-stained smears are not recommended in the diagnosis of endocervical, rectal, cutaneous, and asymptomatic male urethral infections. Because of the presence of nonpathogenic *Neisseria* in the pharynx, the Gram stain is not useful in the diagnosis of pharyngeal infection.[1,10,12–14]

Although no longer considered the most sensitive of diagnostic tests for gonorrhea, culture is considered the test of choice because

TABLE 126-3 Presentation of Gonorrhea Infections

	Males	Females
General	Incubation period 1–14 days Symptom onset in 2–8 days	Incubation period 1–14 days Symptom onset in 10 days
Site of infection	Most common: urethra Others: rectum (usually caused by rectal intercourse in MSM), oropharynx, eye	Most common: endocervical canal Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	Can be asymptomatic or minimally symptomatic Urethral infection: dysuria and urinary frequency Anorectal infection: asymptomatic to severe rectal pain Pharyngeal infection: asymptomatic to mild pharyngitis	Can be asymptomatic or minimally symptomatic Endocervical infection: usually asymptomatic or mildly symptomatic Urethral infection: dysuria, urinary frequency Anorectal and pharyngeal infection; symptoms same as for men
Signs	Purulent urethral or rectal discharge can be scant to profuse Anorectal: pruritus, mucopurulent discharge, bleeding	Abnormal vaginal discharge or uterine bleeding; purulent urethral or rectal discharge can be scant to profuse
Complications	Rare (epididymitis, prostatitis, inguinal lymphadenopathy, urethral stricture) Disseminated gonorrhea	Pelvic inflammatory disease and associated complications (i.e., ectopic pregnancy, infertility) Disseminated gonorrhea (3 times more common than in men)

MSM, men who have sex with men.

of its high specificity in medicolegal situations (e.g., suspected abuse, rape); in diagnosing anorectal, pharyngeal, and conjunctival infections; and in screening populations with a low prevalence. Anatomic sites to be cultured depend on the individual's sexual preferences and body areas exposed. In women, because the urethra and other sites are rarely the sole locus of infection, cervical cultures produce the highest yield and frequently are performed in conjunction with rectal cultures. Urethral cultures are recommended in women who have had hysterectomies and heterosexual men.[1,10–14]

Because technical constraints and cost preclude the use of culture techniques in many office settings and clinics, alternative methods of diagnosis have been developed, including enzyme immunoassay, DNA probe techniques, and nucleic acid amplification techniques (NAATs). With the exception of Gram stain for symptomatic gonococcal urethritis, these tests offer increased sensitivity and/or specificity over both Gram stain and culture.[10,13,14] Additionally, many of these tests can provide a more rapid means of diagnosis than culture. Of particular clinical importance is the high sensitivity of NAATs for detecting *N. gonorrhoeae* using noninvasive specimens (e.g., self-collected urine specimens, vaginal swabs). This technology is also being used to concurrently test for *C. trachomatis* using a single specimen. However, a major drawback of NAATs is their inability to provide resistance data on isolated gonococcal strains.[1,14,15]

TREATMENT

Gonorrhea

1 With the CDC recommendation in 2007 that fluoroquinolones no longer be considered a preferred treatment of gonorrhea because of the increasing rate of resistance, ceftriaxone and cefixime are now the only agents included in the recommended regimens for gonorrhea treatment.[16] (Table 126–4). These regimens have documented efficacy in the treatment of urethral, cervical, rectal, and pharyngeal infections. Coexisting chlamydial infection, which is documented in up to 50% of women and 20% of men with gonorrhea, constitutes the major cause of postgonococcal urethritis, cervicitis, and salpingitis in patients treated for gonorrhea for whom concurrent chlamydial infection has not been ruled out.[1,14] As a result, concomitant treatment with doxycycline or azithromycin is recommended in all patients treated for gonorrhea. Although none

TABLE 126-4 Treatment of Gonorrhea

Type of Infection	Recommended Regimens[a]	Alternative Regimens[b]
Uncomplicated infections of the cervix, urethra, and rectum in adults[c,d]	Ceftriaxone 125 mg IM once,[e] or cefixime 400 mg PO once (tablet or suspension) *plus* A treatment regimen for presumptive *C. trachomatis* coinfection if chlamydial infection has not been ruled out (see Table 126–8)	Spectinomycin 2 g IM once,[f] or ceftizoxime 500 mg IM once, or cefotaxime 500 mg IM once, or cefoxitin 2 g IM once with probenecid 1 g PO once *plus* A treatment regimen for presumptive *C. trachomatis* coinfection if chlamydial infection has not been ruled out (see Table 126–8)
Gonococcal infections in pregnancy	Ceftriaxone 125 mg IM once,[g,h] or cefixime 400 mg PO once (tablet or suspension) *plus* A recommended treatment regimen for presumptive *C. trachomatis* infection during pregnancy,[h] if chlamydial infection has not been ruled out (see Table 126–8)	Spectinomycin 2 g IM once,[f] or ceftizoxime 500 mg IM once, or cefotaxime 500 mg IM once, or cefoxitin 2 g IM once with probenecid 1 g PO once *plus* A recommended treatment regimen for presumptive *C. trachomatis* infection during pregnancy,[h] if chlamydial infection has not been ruled out (see Table 126–8)
Disseminated gonococcal infection in adults (>45 kg)[h,i,j,k]	Ceftriaxone 1 g IM or IV every 24 hours[k]	Cefotaxime 1 g IV every 8 hours[k] or ceftizoxime 1 g IV every 8 hours,[k] or spectinomycin 2 g IM every 12 hours[f,k]
Uncomplicated infections of the cervix, urethra, and rectum in children (<45 kg)	Ceftriaxone 125 mg IM once[l]	Spectinomycin 40 mg/kg IM once (not to exceed 2 g)[f]
Gonococcal conjunctivitis in adults	Ceftriaxone 1 g IM once[m]	
Ophthalmia neonatorum	Ceftriaxone 25–50 mg/kg IV or IM once (not to exceed 125 mg)	
Infants born to mothers with gonococcal infection (prophylaxis)	Erythromycin (0.5%) ophthalmic ointment in a single application[n]; or Tetracycline (1%) ophthalmic ointment in a single application[n,o]	

CDC, Centers for Disease Control and Prevention; *C. trachomatis*, *Chlamydia trachomatis*; PO, orally.

[a]Recommendations are those of the CDC.

[b]A number of other antimicrobials have demonstrated efficacy in treating uncomplicated gonorrhea but are not included in the CDC guidelines.

[c]Treatment failures are usually caused by reinfection and necessitate patient education and sex-partner referral; additional treatment regimens for gonorrhea and chlamydia infections should be administered. Epididymitis should be treated for 10 days (see Table 126–8).

[d]Patients allergic to β-lactams should receive a quinolone. Persons unable to tolerate a β-lactam (penicillin or cephalosporin) or a quinolone should receive spectinomycin.

[e]Also recommended for the treatment of uncomplicated infections of the pharynx in combination with a treatment regimen for presumptive *C. trachomatis* infection, if chlamydial infection has not been ruled out.

[f]Spectinomycin is currently not available in the United States (January 9, 2010).

[g]Another recommended IM or PO cephalosporin also can be used.

[h]Tetracyclines are contraindicated during pregnancy.

[i]Patients treated with one of the recommended regimens should be treated with doxycycline or azithromycin for possible coexistent chlamydial infection.

[j]Patients with gonococcal meningitis should be treated for 10 to 14 days and those with endocarditis for at least 4 weeks with ceftriaxone 1–2 g IV every 12 hours.

[k]All treatment regimens should be continued for 24–48 hours after improvement begins; at this time therapy can be switched to one of the following oral regimens to complete a 7-day course of treatment: cefixime 400 mg PO twice daily (tablet or suspension) or spectinomycin 2 g IM every 12 hours; fluoroquinolones may be an acceptable alternative if susceptibility can be documented by culture.

[l]Patients with bacteremia or arthritis should receive ceftriaxone 50 mg/kg (max. 1 g) IM or IV once daily for 7 days.

[m]A single lavage of the infected eye should be considered.

[n]Efficacy in preventing chlamydial ophthalmia is unclear.

[o]Tetracycline ophthalmic ointment (1%) is currently not available in the United States (January 9, 2010).

of the single-dose regimens recommended for gonorrhea in the CDC guidelines is effective against chlamydia, azithromycin (2 g) as a single dose is highly effective in eradicating both gonorrhea and chlamydia.[1,17,18]

Although oral therapy with cefixime offers a more patient acceptable alternative to intramuscular ceftriaxone, it may not be preferred for all cases of gonorrhea. Of the regimens of choice, only ceftriaxone is effective in eradicating both gonorrhea and incubating syphilis. Because the overall incidence of concomitant infection with both gonorrhea and syphilis appears low in most areas, selection of ceftriaxone based on this criterion should be considered only in areas in which the incidence of syphilis infection is high. Resistance to the broad-spectrum cephalosporins included in the recommended and alternativeregimens for gonorrhea treatmenthas not been reported. Spectinomycin is the preferred alternative for patients unable to tolerate one of the recommended cephalosporins; however, it is currently not available in the United States. Although some resistance to spectinomycin is reported, its limited use appears to have prevented widespread resistance from developing. Unlike ceftriaxone, spectinomycin has only limited efficacy in treating pharyngeal infections.[1,10,12–15]

CLINICAL CONTROVERSY

Some clinicians advocate that a single 2-g dose of azithromycin should be the treatment of choice for gonorrhea because it is also effective in eradicating concomitant chlamydial infection. However, because of concerns regarding the development of resistance and the relatively high incidence of gastrointestinal side effects, azithromycin is not a recommended first-line therapy.

Pregnant women infected with *N. gonorrhoeae* should be treated with either a cephalosporin or spectinomycin. For presumed or diagnosed concurrent *C. trachomatis* infection, either azithromycin or amoxicillin is the preferred treatment.[1,10,11]

Ceftriaxone is the recommended therapy for DGI, gonococcal meningitis, endocarditis, and any type of gonococcal infection in children. In cases of DGI, patients should be hospitalized and treated initially with one of the recommended parenteral antibiotics (see Table 126–4). Although marked improvement is usually noted within 48 hours of initiating therapy, treatment should be continued as an outpatient with one of the recommended oral antibiotics to complete at least 7 days of antibiotic therapy.[1,13,14] Gonococcal ophthalmia is highly contagious in adults and neonates and requires IM ceftriaxone therapy. Single-dose therapy is adequate for gonococcal conjunctivitis, although some physicians recommend continuing therapy until cultures are negative at 48 to 72 hours. Topical antibiotics are not sufficiently effective when used alone for ocular infections and are not necessary with appropriate systemic therapy. Infants with either type of ophthalmologic infection should be evaluated for signs of DGI.[1,10,13–14,19]

Treatment of gonorrhea during pregnancy is essential to prevent ophthalmia neonatorum. Gonococcal infection in newborns results primarily from passage through an infected birth canal, but it also can be transmitted in utero. Ophthalmia neonatorum is the most common ophthalmic infection in newborns (1.6%–12%), although membranes of the vagina, pharynx, or rectum also can become colonized. Conjunctival involvement usually develops within 7 days of delivery and is characterized by intense, bilateral conjunctival inflammation with chemosis. If not treated promptly, corneal ulceration and blindness can develop. Because the law in most states requires neonatal prophylaxis with topical ocular antimicrobials, gonococcal ophthalmia neonatorum is rare in the United States. The CDC recommends that either erythromycin (0.5%) ophthalmic ointment or tetracycline (1%) ophthalmic ointment be instilled in each conjunctival sac immediately postpartum. At present, tetracycline ophthalmic ointment is not commercially available in the United States.[1,10–14,19]

EVALUATION OF THERAPEUTIC OUTCOMES

Although some clinicians recommend obtaining follow-up cultures at least 3 days after treatment, combination gonorrhea and chlamydial therapy rarely results in treatment failures, and routine follow-up of patients treated with a regimen included in the CDC guidelines is not recommended. Persistence of symptoms following any treatment requires culture of the site(s) of gonorrheal infection, as well as susceptibility testing if gonococci are isolated. In most cases, the presence of gonococci indicates reinfection rather than treatment failure and reflects the need for improved patient education and sex partner referral. Persistence of symptoms also can be caused by other infectious causes, such as *C. trachomatis*.[1,10–15]

SYPHILIS

EPIDEMIOLOGY AND ETIOLOGY

Although the 13,500 cases of primary and secondary syphilis reported in the United States in 2008 is still relatively low, this number represents the highest number of cases reported in over a decade.[9] In addition to being highly contagious, syphilis is of major concern because, if left untreated, it can progress to a chronic systemic disease that can be fatal or seriously disabling.[21–29]

Syphilis usually is acquired by sexual contact with infected mucous membranes or cutaneous lesions, although on rare occasions it can be acquired by nonsexual personal contact, accidental inoculation, or blood transfusion. The causative organism of syphilis is *Treponema pallidum*, a spirochete. The risk of acquiring syphilis from an infected individual after a single sexual encounter is approximately 50% to 60%. After sexual contact, the organism penetrates the intact mucous membrane or a break in the cornified epithelium, and spirochetemia occurs.[21,24,25–29]

There is strong evidence of an association between syphilis and HIV infection. Syphilis, similar to other sexually transmitted genital ulcer diseases, can increase the risk of acquiring HIV in exposed individuals. Also, immunologic defects in HIV-infected individuals can produce an atypical serologic response to syphilis. In particular, the possibility of delayed seroreactivity, markedly elevated serologic titers, and increased false-positive results could complicate the diagnosis, as well as assessment of treatment efficacy, in HIV-positive individuals infected with syphilis. Furthermore, anecdotal evidence suggests that compromised immune function can result in an accelerated progression of syphilis, particularly to neurosyphilis, requiring more aggressive antibiotic therapy in comparison with an immunocompetent host. As a result of this association, the CDC recommends that all patients diagnosed with syphilis be tested for HIV infection.[1,22–24,26,27]

CLINICAL PRESENTATION

The clinical presentation of syphilis is varied with progression through multiple stages possible in untreated or inadequately treated patients (Table 126–5).

TABLE 126-5 Presentation of Syphilis Infections

General	
Primary	Incubation period 10–90 days (mean, 21 days)
Secondary	Develops 2–8 weeks after initial infection in untreated or inadequately treated individuals
Latent	Develops 4–10 weeks after secondary stage in untreated or inadequately treated individuals
Tertiary	Develops in approximately 30% of untreated or inadequately treated individuals 10–30 years after initial infection
Site of infection	
Primary	External genitalia, perianal region, mouth, and throat
Secondary	Multisystem involvement secondary to hematogenous and lymphatic spread
Latent	Potentially multisystem involvement (dormant)
Tertiary	CNS, heart, eyes, bones, and joints
Signs and symptoms	
Primary	Single, painless, indurated lesion (chancre) that erodes, ulcerates, and eventually heals (typical); regional lymphadenopathy is common; multiple, painful, purulent lesions possible but uncommon
Secondary	Pruritic or nonpruritic rash, mucocutaneous lesions, flulike symptoms, lymphadenopathy
Latent	Asymptomatic
Tertiary	Cardiovascular syphilis (aortitis or aortic insufficiency), neurosyphilis (meningitis, general paresis, dementia, tabes dorsalis, eighth cranial nerve deafness, blindness), gummatous lesions involving any organ or tissue

Primary Syphilis

The primary stage, characterized by the appearance of a chancre on cutaneous or mucocutaneous tissue exposed to the organism, is highly infectious. Even without treatment, chancres persist only for 1 to 8 weeks before healing spontaneously. Because syphilitic chancres can be confused with other infectious etiologies, appropriate diagnostic testing is important.[21–24,26,28]

Secondary Syphilis

The secondary stage of syphilis is characterized by a variety of mucocutaneous eruptions resulting from widespread hematogenous and lymphatic spread of *T. pallidum*. Skin lesions can be either generalized or localized to a small portion of the body and, with the exception of follicular lesions, are nonpruritic. Generalized lymphadenopathy also is seen in the majority of patients, as are nonspecific symptoms such as mild and transitory malaise, fever, pharyngitis, headache, anorexia, and arthralgia. If untreated, secondary syphilis disappears in 4 to 10 weeks; however, lesions can recur at any time within 4 years.[21–28]

Latent Syphilis

By definition, persons with a positive serologic test for syphilis but with no other evidence of disease have latent syphilis. Latent syphilis is further divided into early and late latency. During early latency, the patient is considered potentially infectious because of the 25% risk of spontaneous mucocutaneous relapse. The U.S. Public Health Service defines early latency as 1 year from the onset of infection, although other investigators propose a longer interval, such as 2 to 4 years. With the exception of pregnancy in which the mother can pass the disease to the fetus, late latency is considered noninfectious, although the patient remains a host.[1,21–28]

Most untreated patients with late latent syphilis have no further sequelae; however, approximately 25% to 30% progress either to neurosyphilis or to late syphilis with clinical manifestations other than neurosyphilis. Treatment of all patients with latent syphilis is essential because there is no way to predict which patients will have progression of their disease.[21–28]

Tertiary Syphilis and Neurosyphilis

If left untreated, syphilis can slowly produce an inflammatory reaction in virtually any organ in the body. Manifestations of this disease progression were referred to previously as *tertiary syphilis*. These clinical manifestations now are differentiated into two subgroups based on the presence or absence of central nervous system (CNS) involvement: neurosyphilis or tertiary syphilis (i.e., gumma and cardiovascular syphilis).[1,21–27]

Currently, the term *neurosyphilis* encompasses any patient with cerebrospinal fluid (CSF) abnormalities consistent with CNS infection. Approximately 40% of patients with primary or secondary syphilis exhibit such abnormalities, although most remain asymptomatic. Persistence of CSF abnormalities into late latency is associated with a greater risk of progression to symptomatic neurosyphilis. Although data are conflicting, some investigators suggest that HIV-infected patients are at greater risk of developing symptomatic neurosyphilis than patients with intact immune systems.[1,21–25]

Rarely seen, the most common manifestations of disease progression from late latency are benign gumma formation and cardiovascular syphilis. The gumma, a nonspecific granulomatous lesion, is the classic lesion of late syphilis and develops in 50% of patients with disease progression. These chronic, destructive lesions characteristically infiltrate the skin, bone, soft tissue, and liver but can be found in any organ or tissue. Gummas of critical organs, such as the heart or brain, can be fatal.[1,21–24,27]

Congenital Syphilis

In pregnant women with syphilis, *T. pallidum* can cross the placenta at any time during pregnancy. The risk of fetal infection is greatest in pregnant women with primary and secondary syphilis and declines in pregnant women with late disease. Transmission of syphilis during pregnancy occurs primarily transplacentally and can result in fetal death, prematurity, or congenital syphilis. Symptoms can be seen during the first months of life (early congenital syphilis) or later in childhood or adolescence (late congenital syphilis). Manifestations of early congenital syphilis resemble those of secondary syphilis, whereas those of late congenital syphilis correspond to the tertiary stage in adults.[22–24]

DIAGNOSIS

Because *T. pallidum* is difficult to culture in vitro, diagnosis is based primarily on microscopic examination of serous material from a suspected syphilitic lesion or on results from serologic testing. In primary syphilis, diagnosis is established by the presence of *T. pallidum* on dark-field microscopic examination of material from cutaneous lesions and enlarged lymph nodes in patients with secondary syphilis. In incubating syphilis, confirmation frequently is by dark-field microscopic examination because serologic tests can be unreactive early in the disease. Another method of direct microscopic examination, the direct fluorescent antibody (test) for *T. pallidum* (DFA-TP), which uses monoclonal or polyclonal antibodies specific for *T. pallidum,* has greater specificity and sensitivity than dark-field examination, and does not require the immediate examination of fresh specimens.[24–29]

Serologic tests are the mainstay in the diagnosis of syphilis and traditionally are categorized as nontreponemal or treponemal. Common nontreponemal tests include the Venereal Disease Research Laboratory (VDRL) slide test, rapid plasma reagin (RPR)

card test, unheated serum reagin (USR) test, and the toluidine red unheated serum test (TRUST). Nontreponemal tests, which are inexpensive and easily performed, rely on the detection of treponemal antibodies directed against an alcoholic solution of cardiolipin, lecithin, and cholesterol contained in these tests. A positive nontreponemal test can indicate the presence of any stage of syphilis or congenital syphilis, although incubating syphilis and very early primary syphilis produce a negative reaction; however, because they are nonspecific tests, false-positive reactions occur, making them inappropriate to confirm the diagnosis alone. Transiently false-positive results can be seen in patients with acute febrile illnesses, after immunizations, and during pregnancy. Chronic false-positive results are commonly associated with heroin addiction, aging, chronic infections, autoimmune diseases, and malignant disease. In some cases, false-positive reactions are familial and are related to abnormal serum globulin levels.[23–29]

Nontreponemal tests are used primarily as screening tests; however, because *T. pallidum* antibody titers also can be quantitated by testing serial dilutions of the patient's serum for reactivity, they are useful in following the progression of the disease, recovery after therapy, and possible reinfection. Because antibody titers vary to some extent between tests, it is important that sequential serologic testing be performed using the same method each time. In patients treated successfully for primary and secondary syphilis, nontreponemal tests almost always will return to seronegativity. If these tests are going to return to negative in patients with early latent syphilis, they will do so within the first 4 years after adequate therapy; patients with disease of longer duration usually remain seropositive for life. In addition to their use in serologic testing, nontreponemal tests often are used on CSF to diagnose neurosyphilis.[23–29]

In some patients with secondary syphilis, a prozone phenomenon occurs that produces a negative VDRL test despite the presence of high reaginic antibody titers. This is corrected by diluting the patient's serum prior to testing.[26,27] For HIV-positive individuals with syphilis, the reactivity of nontreponemal tests can vary depending on the stage of the HIV infection. In the early stages, reaginic titers higher than in non–HIV-infected patients have been seen, resulting in the prozone phenomenon. During the later stages of HIV infection, however, when immune function deteriorates to a greater extent, serologic responses can be reduced or delayed. As a result, the diagnosis of syphilis in HIV-infected individuals can be more difficult.[1,24–29]

In diagnosing all stages of syphilis, treponemal tests are more sensitive than nontreponemal tests. Because these tests are technically more demanding and are more expensive, they are used primarily as confirmatory rather than as screening tests. For many years, the fluorescent treponemal antibody absorption (FTA-ABS) test was the most frequently used treponemal test. The FTA-ABS test uses the *T. pallidum* antigen to detect specific antibodies to treponemal organisms. However, the FTA-ABS test has largely been replaced by card assays such as the *T. pallidum* hemagglutination assay (TPHA), the micro-hemagglutination assay for antibodies to *T. pallidum* (MHA-TP), and the *T. pallidum* particle agglutination assay (TPPA) which can be automated and are less expensive to perform. Despite adequate antibiotic therapy for any stage of syphilis, the antibody tests, usually remain reactive for life and therefore are not useful in assessing serologic response to therapy, relapse, or reinfection.[1,24–29]

Several enzyme immunoassays for *T. pallidum* have become available and are gaining wide use as confirmatory tests. Polymerase chain reaction (PCR)-based tests also are being investigated, particularly in situations in which serologic testing has poor sensitivity and specificity (e.g., congenital syphilis, early primary syphilis, and neurosyphilis). Additionally, multiplex PCR tests that can identify the presence of *T. pallidum*, herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 1 (HSV-2), and *Haemophilus ducreyi* from genital ulcer specimens are under study.[22–24,29]

TREATMENT

Syphilis

Table 126–6 presents the CDC's treatment recommendations.[1] Parenteral penicillin G is the treatment of choice for all stages of syphilis. Because *T. pallidum* multiplies slowly, single doses of short- or intermediate-acting penicillins do not provide the prolonged, low-level exposure to penicillin required for eradication of the treponeme. As a result, benzathine penicillin G is the only penicillin effective for single-dose therapy.[1,22–28]

The recommended treatment for syphilis of less than 1 year's duration is benzathine penicillin G 2.4 million units as a single dose. Although the relapse rate for this regimen is less than 3%, some investigators advocate that 2.4 million units be administered once a week for 2 consecutive weeks. In patients with syphilis of longer than 1 year's duration and normal CSF examination, benzathine penicillin G is administered weekly for three successive doses. Although not specifically recommended by the CDC, this three-dose regimen is used by some experts to treat HIV-infected patients with syphilis of less than 1 year's duration based on data suggesting a greater risk of treatment failure with single-dose therapy.[1,24–28]

CLINICAL CONTROVERSY

Some experts even prefer to treat all patients with syphilis of less than 1 year's duration with the three-dose regimen because single-dose therapy is not consistently effective in eradicating treponemes from the CSF; this is of primary concern in patients with undiagnosed CSF involvement, such as HIV-infected individuals.

Patients with abnormal CSF findings should be treated as having neurosyphilis. Preferred regimens for neurosyphilis provide treatment over 10 to 14 days with parenteral penicillin G administered every 4 hours. Benzathine penicillin G alone in standard weekly doses and procaine penicillin G in doses under 2.4 million units do not consistently provide treponemicidal levels in the CSF and have resulted in treatment failures. Because *T. pallidum* resistance to penicillin has not emerged, the primary need for alternative drugs in treating syphilis is for penicillin-allergic patients.[1,24–28]

2 Alternative regimens recommended for penicillin-allergic patients are doxycycline 100 mg orally twice daily or tetracycline 500 mg orally 4 times daily for 2 to 4 weeks depending on the duration of syphilis infection. These regimens should be used only in cases of documented penicillin allergy, and given concerns regarding patient compliance with these regimens, follow-up serologic testing is of particular importance.[1,24–28]

Other antibiotics used successfully in treating syphilis include various β-lactam antibiotics; however, none offers significant advantages over benzathine penicillin G. Even though ceftriaxone is considered effective in eradicating incubating syphilis when given as a single 125-mg dose, higher doses and more frequent administration (e.g., 1,000 mg daily for 8 to 10 days) appear necessary for more advanced syphilis, and treatment failures are reported in HIV-infected patients. Although azithromycin 2 g as a single dose produces good results in patients with early syphilis, treatment failures and resistance to azithromycin are reported.[1,21,24–28]

TABLE 126-6 Drug Therapy and Follow-up of Syphilis

Stage/Type of Syphilis	Recommended Regimens[a,b]	Follow-up Serology
Primary, secondary, or early latent syphilis (<1 year's duration)	Benzathine penicillin G 2.4 million units IM in a single dose[c]	Quantitative nontreponemal tests at 6 and 12 months for primary and secondary syphilis; at 6, 12, and 24 months for early latent syphilis[d]
Late latent syphilis (>1 year's duration) or latent syphilis of unknown duration	Benzathine penicillin G 2.4 million units IM once a week for 3 successive weeks (7.2 million units total)	Quantitative nontreponemal tests at 6, 12, and 24 months[e]
Neurosyphilis	Aqueous crystalline penicillin G 18–24 million units IV (3–4 million units every 4 hours or by continuous infusion) for 10–14 days[f] *or* Aqueous procaine penicillin G 2.4 million units IM daily plus probenecid 500 mg PO four times daily, both for 10–14 days[f]	CSF examination every 6 months until the cell count is normal; if it has not decreased at 6 months or is not normal by 2 years, retreatment should be considered
Congenital syphilis (infants with proven or highly probable disease)	Aqueous crystalline penicillin G 50,000 units/kg IV every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days *or* Procaine penicillin G 50,000 units/kg IM daily for 10 days	Serologic follow-up only recommended if antimicrobials other than penicillin are used
Penicillin-allergic patients[g]		
Primary, secondary, or early latent syphilis	Doxycycline 100 mg PO 2 times daily for 14 days[g,h] *or* Tetracycline 500 mg PO 4 times daily for 14 days[h] Ceftriaxone 1 g IM or IV daily for 8–10 days	Same as for non–penicillin-allergic patients
Late latent syphilis (>1 year's duration) or syphilis of unknown duration	Doxycycline 100 mg PO twice a day for 28 days[h,i] *or* Tetracycline 500 mg PO 4 times daily for 28 days[h,i]	Same as for non–penicillin-allergic patients

CDC, Centers for Disease Control and Prevention; CSF, cerebrospinal fluid; PO, orally.
[a]Recommendations are those of the CDC.
[b]The CDC recommends that all patients diagnosed with syphilis be tested for HIV infection.
[c]Some experts recommend multiple doses of benzathine penicillin G or other supplemental antibiotics in addition to benzathine penicillin G in HIV-infected patients with primary or secondary syphilis; HIV-infected patients with early latent syphilis should be treated with the recommended regimen for latent syphilis of more than 1 year's duration.
[d]More frequent follow-up (i.e., 3, 6, 9, 12, and 24 months) recommended for HIV-infected patients.
[e]More frequent follow-up (i.e., 6, 12, 18, and 24 months) recommended for HIV-infected patients.
[f]Some experts administer benzathine penicillin G 2.4 million units IM once per week for up to 3 weeks after completion of the neurosyphilis regimens to provide a total duration of therapy comparable to that used for late syphilis in the absence of neurosyphilis.
[g]For nonpregnant patients; pregnant patients should be treated with penicillin after desensitization.
[h]Pregnant patients allergic to penicillin should be desensitized and treated with penicillin.
[i]Limited data suggest that ceftriaxone my be effective, although the optimal dosage and treatment duration are unclear.

For pregnant patients, penicillin is the treatment of choice at the dosage recommended for that particular stage of syphilis. To ensure treatment success and prevent transmission to the fetus, some experts advocate an additional IM dose of benzathine penicillin G 2.4 million units 1 week after completion of the recommended regimen. In women allergic to penicillin, safe and effective alternatives are not available; therefore, skin testing should be performed to confirm a penicillin allergy. It is recommended that women with positive skin tests undergo penicillin desensitization and receive the appropriate treatment regimen for their stage of disease.[1,22–24]

Most patients treated for primary and secondary syphilis experience the Jarisch-Herxheimer reaction after treatment. This benign, self-limiting reaction is characterized by flulike symptoms, such as transient headache, fever, chills, malaise, arthralgia, myalgia, tachypnea, peripheral vasodilation, and aggravation of syphilitic lesions. The exact mechanism of the reaction is unknown, although proposed etiologies, including immunologic mechanisms and release of endotoxin or other toxic treponemal products, are not substantiated. The Jarisch-Herxheimer reaction is independent of the drug and dose used and should not be confused with penicillin allergy. It usually begins within 2 to 4 hours of initiating therapy, peaks at 8 hours, and is complete within 12 to 24 hours. Most reactions can be managed symptomatically with analgesics, antipyretics, and rest. Steroids and antihistamines have been administered prior to initiation of syphilitic therapy but are of limited value.[1,22–24]

EVALUATION OF THERAPEUTIC OUTCOMES

Table 126–6 lists the CDC recommendations for serologic follow-up of patients treated for syphilis.[1] Quantitative nontreponemal tests should be performed at 6 and 12 months in all patients treated for primary and secondary syphilis and at 6, 12, and 24 months for early and late latent disease. The CDC recommends more frequent monitoring of HIV-infected individuals (i.e., 3, 6, 9, 12, and 24 months after therapy). In general, the time to reach seronegativity is proportional to the duration of the disease. Table 126–6 also includes specific testing recommendations for other stages of syphilis. Despite adequate therapy, some patients can remain seropositive based on nontreponemal test results. In these cases, stabilization of low antibody titers is indicative of adequate therapy. For women treated during pregnancy, monthly quantitative nontreponemal tests are recommended in those at high risk of reinfection.[22–24]

CHLAMYDIA TRACHOMATIS

EPIDEMIOLOGY AND ETIOLOGY

Based on CDC data, the number of reported cases of chlamydia infection, the most frequently reported infectious disease in the United States, has almost doubled in the past 10 years.[1,9] Although this most likely is a result of improved screening and detection, it can

also represent a true increase in the infection rate. Chlamydial infections represent the most common cause of nongonococcal urethritis (NGU), accounting for as much as 50% of such infections.[1,30–34]

PATHOPHYSIOLOGY

C. trachomatis is an obligate intracellular parasite that shares properties of both viruses and bacteria. Like viruses, chlamydiae require cellular material from host cells for replication; however, unlike viruses, chlamydiae maintain their cellular identity throughout development. Although *C. trachomatis* lacks a cell-wall peptidoglycan, its major outer membrane is similar to gram-negative bacteria. At least 18 serovars (subspecies) of *C. trachomatis* exist, of which only the lymphogranuloma venereum strains produce potentially invasive infections. The remaining serovars are involved primarily with superficial infection of epithelial cells.[30–34]

The risk of transmissibility of chlamydia after exposure is unknown but is believed to be less than that following exposure to *N. gonorrhoeae*. Coinfection with chlamydia occurs in a substantial number of individuals with gonorrhea and all individuals diagnosed with *N. gonorrhoeae* should be assumed also to have *C. trachomatis* present, if chlamydial infection has not been ruled out.[1] Of major concern is that chlamydial infections are associated with a significantly increased risk of acquiring HIV infection. In addition to genital infections, ocular infections in adults owing to autoinoculation and infants owing to vaginal delivery through an infected birth canal are reported. Pharyngeal and rectal infections can develop secondary to orogenital or receptive anal intercourse, respectively, with an infected individual.[1,30–37]

CLINICAL PRESENTATION

In comparison with gonorrhea, chlamydial genital tract infections are more frequently asymptomatic, and when present, symptoms tend to be less noticeable. Urethral discharge usually is less profuse and more mucoid or watery than the urethral discharge associated with gonorrhea.[31–34] Table 126–7 summarizes the usual clinical presentation of chlamydial infections.

TABLE 126-7 Presentation of *Chlamydia* Infections

	Males	Females
General	Incubation period: 35 days Symptom onset: 7–21 days	Incubation period: 7–35 days Usual symptom onset: 7–21 days
Site of infection	Most common: urethra Others: rectum (receptive anal intercourse), oropharynx, eye	Most common: endocervical canal Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	More than 50% of urethral and rectal infections are asymptomatic Urethral infection: mild dysuria, discharge Pharyngeal infection: asymptomatic to mild pharyngitis	More than 66% of cervical infections are asymptomatic Urethral infection: usually sub-clinical; dysuria and frequency uncommon Rectal and pharyngeal infection: symptoms same as for men
Signs	Scant to profuse, mucoid to purulent urethral or rectal discharge Rectal infection: pain, discharge, bleeding	Abnormal vaginal discharge or uterine bleeding, purulent urethral or rectal discharge can be scant to profuse
Complications	Epididymitis, Reiter syndrome (rare)	Pelvic inflammatory disease and associated complications (i.e., ectopic pregnancy, infertility) Reiter syndrome (rare)

Similar to gonorrhea, chlamydia can be transmitted to an infant during contact with infected cervicovaginal secretions. Nearly two-thirds of infants acquire chlamydial infection after endocervical exposure, with the primary morbidity associated with seeding of the infant's eyes, nasopharynx, rectum, or vagina. In exposed infants, neonatal conjunctivitis develops in as many as 50%, and pneumonia develops in up to 16%. Inclusion conjunctivitis in newborns is usually self-limited, but it can result in scarring and micropannus of the cornea. Interstitial pneumonitis occurring secondary to carriage in the nasopharynx typically is mild, but it can be severe and require hospitalization.[1,31–34,36]

DIAGNOSIS

3 Because of the high rate of asymptomatic disease and the high prevalence of chlamydial infection in sexually active females 25 years of age or younger and sexually active women with new sex partners or multiple sex partners, the CDC recommends routine annual screening in these individuals. Laboratory confirmation of chlamydial infection is important because of the relative lack of specificity of symptoms when present.[1]

Cell culture is the reference standard against which all other diagnostic tests are measured. Because chlamydiae are obligate intracellular parasites, specimens for culture must be obtained from endocervical (women) or urethral (men) epithelial cell scrapings rather than from urine or urethral discharges. Although tissue culture techniques have close to 100% specificity, the sensitivity is reported to be as low as 70% in part because of problems of improper specimen collection, transport, or processing. Because of the technical demands, expense, and length of time until results are available (3–7 days), culture is not used widely for diagnostic purposes today. However, culture remains the diagnostic standard in medicolegal cases such as sexual assault and child abuse because of its high specificity and ability to detect only viable organisms.[31–34,37–40]

Tests that detect chlamydial antigens and nucleic acid provide more rapid results, are technically less demanding to perform, are less costly, and in some situations have greater sensitivity than culture. Commonly used nonculture tests for detection of *C. trachomatis* are the enzyme immunosorbent assay (EIA), DNA hybridization probe, and NAATs.[32,34,37,39]

Although still widely used both as rapid office tests and as laboratory-based tests, EIA methods for diagnosis of *C. trachomatis* are no longer recommended because of their poor sensitivity in comparison to NAATs. NAATs, which can detect small amounts of chlamydial DNA, are highly sensitive and specific for detecting infection in urogenital and anal specimens, as well as in urine. Use of self-collected vaginal or anal specimens or first-void urine samples offers greater patient acceptability, particularly when used to screen asymptomatic individuals. A further advantage of tests that can screen urine for the presence of infection is that up to 30% of women are reported to have urethral infection only, which would be missed using a test on endocervical samples. Because of their ability to detect as little as a single gene copy in a specimen, nucleic acid residues that persist following successful antibiotic therapy of a chlamydial infection can result in a false-positive test for several weeks following eradication of the organism.[33,34]

TREATMENT

Chlamydia

A number of antimicrobials, including tetracyclines, macrolides, azithromycin, and some fluoroquinolones, display good in vitro and in vivo activity against *C. trachomatis*. In most clinical

TABLE 126-8 Treatment of *Chlamydial* Infections

Infection	Recommended Regimens[a]	Alternative Regimen
Uncomplicated urethral, endocervical, or rectal infection in adults	Azithromycin 1 g PO once, or doxycycline 100 mg PO twice daily for 7 days	Ofloxacin 300 mg PO twice daily for 7 days, or levofloxacin 500 mg PO once daily for 7 days, or erythromycin base 500 mg PO 4 times daily for 7 days, or erythromycin ethyl succinate 800 mg PO 4 times daily for 7 days
Urogenital infections during pregnancy	Azithromycin 1 g PO as a single dose or amoxicillin 500 mg PO 3 times daily for 7 days	Erythromycin base 500 mg PO 4 times daily for 7 days, or erythromycin base 250 mg PO 4 times daily for 14 days, or erythromycin ethyl succinate 800 mg PO 4 times daily for 7 days (or 400 mg PO 4 times daily for 14 days)
Conjunctivitis of the newborn or pneumonia in infants	Erythromycin base 50 mg/kg/day PO in four divided doses for 14 days[b]	

CDC, Centers for Disease Control and Prevention; PO, orally.
[a]Recommendations are those of the CDC.
[b]Topical therapy alone is inadequate and is unnecessary when systemic therapy is administered.

trials, cure rates exceeding 90% are reported for these agents. All these antimicrobials also appear to have good efficacy against *Ureaplasma urealyticum*, the second most common cause of NGU.[31–34]

Azithromycin 1 g orally as a single dose and doxycycline 100 mg orally twice daily for 7 days are the regimens of choice for the treatment of uncomplicated chlamydial infections[1] (Table 126–8). Because of its prolonged serum and tissue half-life, azithromycin is the only single-dose therapy that is effective in treating *C. trachomatis*. Of the fluoroquinolones, ofloxacin and levofloxacin are included in the CDC recommendations, but neither appears to offer an advantage over other first-line or alternative therapies. Although ciprofloxacin and some other fluoroquinolones have activity against *C. trachomatis* and *U. urealyticum*, high dosages have not consistently eradicated chlamydial infections.[1,31–37]

For pregnant women with chlamydial urogenital infections, treatment can reduce the risk of pregnancy complications and transmission to the newborn significantly. Because the use of tetracyclines and fluoroquinolones is contraindicated during pregnancy, azithromycin and amoxicillin are the recommended drug treatments (see Table 126–8). When compliance with a multiday regimen is a concern, azithromycin is the preferred treatment in women, regardless of pregnancy status. It is recommended that post-treatment cultures be obtained for pregnant patients treated for chlamydial infections to ensure eradication of the infection. Persons treated for chlamydia should abstain from sexual intercourse for 7 days following the initiation of treatment.[1,34–37,41,42]

C. trachomatis transmission during perinatal exposure can result in infections of the eye, oropharynx, lungs, urogenital tract, and rectum of the neonate or infant. Despite their efficacy in preventing gonococcal ophthalmia, topical erythromycin ointment (0.5%), and tetracycline ointment (1%) appear less effective in preventing chlamydial ophthalmia. Additionally, topical therapy has no effect on nasal carriage or colonization of other parts of the infant's body, so the potential for other infections, including pneumonia, remains. Because of the high percentage of treatment failures, topical therapy is not recommended to treat ophthalmia caused by *C. trachomatis*. Instead, an oral erythromycin regimen is recommended.[1,31–34]

EVALUATION OF THERAPEUTIC OUTCOMES

Treatment of chlamydial infections with the recommended regimens is highly effective; therefore, post-treatment laboratory testing is not recommended routinely unless symptoms persist or there are other specific concerns (e.g., pregnancy). Post-treatment tests should not be performed for at least 3 weeks following completion of therapy.[1] When post-treatment tests are positive, they usually represent noncompliance, failure to treat sexual partners, or laboratory error rather than inadequate therapy or resistance to therapy. Infants with pneumonitis should receive follow-up testing because erythromycin is only 80% effective, and a second course of therapy can be necessary.[1,31–34]

GENITAL HERPES

EPIDEMIOLOGY AND ETIOLOGY

Genital herpes infections represent the most common cause of genital ulceration seen in the United States. More than 50 million Americans have genital herpes, and this number is increasing by at least 500,000 each year.[1,43–48] Because of its morbidity, recurrent nature, and potential for complications, as well as its ability to be transmitted asymptomatically, genital herpes is of major public health importance.[45–54] Similar to syphilis and other STDs, the presence of genital herpes lesions is associated with an increased risk of acquiring HIV following exposure.[1,43–49]

PATHOPHYSIOLOGY

Herpes comes from the Greek word meaning "to creep" and is used to describe two distinct but antigenically related serotypes of herpes simplex virus. HSV-1 is associated most commonly with oropharyngeal disease, and HSV-2 is associated most closely with genital disease; however, each virus is capable of causing clinically indistinguishable infections in both anatomic areas.[43–45,48]

Humans are the sole known reservoir for HSV. Infection is transmitted via inoculation of virus from infected secretions onto mucosal surfaces (e.g., urethra, oropharynx, cervix, and conjunctivae) or through abraded skin. Evidence that the virus survives for a limited time on environmental surfaces suggests the possibility of fomitic transfer as a nonvenereal route of transmission.[43–45,48]

The cycle of HSV infection occurs in five stages: primary muco-cutaneous infection, infection of the ganglia, establishment of latency, reactivation, and recurrent infection. After viral inoculation, HSV infection is associated with cytoplasmic granulation, ballooning degeneration of cells, and production of mononucleated giant cells. Initially, the cellular response is predominantly polymorphonuclear, followed by a lymphocytic response. Replication occurs with viral spread to contiguous cells and peripheral sensory nerves. Latency then is established in sensory or autonomic nerve root ganglia. Latency appears to be lifelong, interrupted only by reactivation of the viral infection. It is unclear what factors are important in maintaining latency, but

TABLE 126-9 Presentation of Genital Herpes Infections

General	Incubation period 2–14 days (mean, 4 days) Can be caused by either HSV-1 or HSV-2
Classification of infection	
First-episode primary	Initial genital infection in individuals lacking antibody to either HSV-1 or HSV-2
First-episode nonprimary	Initial genital infection in individuals with clinical or serologic evidence of prior HSV (usually HSV-1) infection
Recurrent	Appearance of genital lesions at some time following healing of first-episode infection
Signs and symptoms	
First-episode infections	Most primary infections are asymptomatic or minimally symptomatic Multiple painful pustular or ulcerative lesions on external genitalia developing over a period of 7–10 days; lesions heal in 2–4 weeks (mean, 21 days) Flulike symptoms (e.g., fever, headache, malaise) during first few days after appearance of lesions Others–local itching, pain or discomfort; vaginal or urethral discharge, tender inguinal adenopathy, paresthesias, urinary retention Severity of symptoms greater in females than in males Symptoms are less severe (e.g., fewer lesions, more rapid lesion healing, fewer or milder systemic symptoms) with nonprimary infections Symptoms more severe and prolonged in the immunocompromised On average viral shedding lasts approximately 11–12 days for primary infections and 7 days for nonprimary infections
Recurrent	Prodrome seen in approximately 50% of patients prior to appearance of recurrent lesions; mild burning, itching, or tingling are typical prodromal symptoms Compared to primary infections, recurrent infections associated with (1) fewer lesions that are more localized, (2) shorter duration of active infection (lesions heal within 7 days), and (3) milder symptoms Severity of symptoms greater in females than in males Symptoms more severe and prolonged in the immunocompromised On average viral shedding lasts approximately 4 days Asymptomatic viral shedding is more frequent during the first year after infection with HSV
Therapeutic implications of HSV-1 vs HSV-2 genital infection	Primary infections caused by HSV-1 and HSV-2 virtually indistinguishable Recurrent infections and subclinical viral shedding are less frequent with HSV-1 Recurrent infections with HSV-2 tend to be more severe
Complications	Secondary infection of lesions; extragenital infection because of autoinoculation; disseminated infection (primarily in immunocompromised patients); meningitis or encephalitis; neonatal transmission

HSV-1, herpes simplex virus type 1; HSV-2, herpes simplex virus type 2.

immune responses and emotional and physical stresses appear important in reactivating latent virus.[43–45,48]

CLINICAL PRESENTATION

The signs and symptoms of genital herpes infection are influenced by many factors, including previous exposure to HSV, viral type, and host factors such as age and site of infection. Because a high percentage of initial and recurrent infections are asymptomatic, and because viral shedding can occur in the absence of apparent lesions or symptoms, identification and education of individuals with genital herpes are essential in controlling its transmission.[43–52] A summary of the clinical presentation of genital herpes is provided in Table 126–9.

Complications

Complications from genital herpes infections result from both genital spread and autoinoculation of the virus and occur most commonly with primary first episodes. Lesions at extragenital sites, such as the eye, rectum, pharynx, and fingers, are not uncommon. CNS involvement is seen occasionally and can take several forms, including an aseptic meningitis, transverse myelitis, or sacral radiculopathy syndrome.[43–52]

A major concern is the effect of genital herpes on neonates exposed during pregnancy. Neonatal herpes is associated with a high mortality and significant morbidity. It is transmitted to the newborn primarily through exposure to HSV in the birth canal but, in rare cases, also is transmitted transplacentally. The risk of transmission during birth appears much greater for first-episode primary infections than for recurrent infections. Neonatal herpes infection has a case-fatality rate of approximately 50%, with a large proportion of surviving infants experiencing significant morbidity, including permanent neurologic damage.[43,44,48]

DIAGNOSIS

Confirmation of a genital herpes infection can be made only with laboratory testing. Tissue culture is the most specific (100%) and sensitive method (80%–90%) of confirming the diagnosis of first-episode genital herpes; however, culture is relatively insensitive in detecting HSV in ulcers in the latter stages of healing and in recurrent infections, as a result, in part, of reduced viral load. Viral culture is expensive and time consuming, and improper collection or transport of specimens can result in false-negative results. In most situations, HSV isolation on tissue culture takes 48 to 96 hours. Following isolation, it is recommended that typing of the virus be performed because of prognostic implications (HSV-1 is associated with a lower rate of asymptomatic and symptomatic recurrence). In instances in which rapid detection is necessary, such as an impending birth, other detection methods can be more useful. Amplified culture techniques that combine cell culture for 24 hours and subsequent staining for HSV antigen have sensitivities and specificities only slightly less than those of culture.[43–48,53–55]

Several serologic tests capable of distinguishing HSV-1 and HSV-2 antibodies are available. These tests detect antibodies to type-specific HSV-1 and HSV-2 proteins gG-1 and gG-2, respectively. Whereas antibody formation begins immediately following a primary herpes infection, complete seroconversion (i.e., complete antibody development) can take several months. Until the full expression of all antigenic determinants of HSV-1 and HSV-2 occurs, these tests are not useful in differentiating HSV-1 and HSV-2 infection. Older antibody detection tests, some of which are still marketed, are unable to distinguish between HSV-1 and HSV-2 owing to the considerable cross-reactivity between the two serotypes. Given the high prevalence of HSV-1 antibody in the adult population, accurate interpretation of positive results is not possible.[43–48,53–55]

PCR assays that detect HSV DNA and differentiate HSV-1 and HSV-2 infections are more sensitive than culture and are considered the diagnostic test of choice for suspected CNS infections (i.e., HSV encephalitis and HSV meningitis). PCR assays are highly sensitive in detecting asymptomatic viral shedding.[43–48,53–55]

Although the diagnosis of genital herpes can be confirmed only by laboratory tests, less stringent diagnostic criteria (e.g., characteristic physical findings or clinical history) frequently are used in clinical practice. A presumptive diagnosis of genital herpes commonly is made based on the presence of dark-field-negative, vesicular, or ulcerative genital lesions. A prior history of similar lesions or recent sexual contact with an individual with similar lesions also is useful in making the diagnosis. Other STDs, including chancroid, lymphogranuloma venereum, and granuloma inguinale, and causes such as trauma, allergic reactions, and bacterial or fungal infections are considered in the differential diagnosis.[43–48,53–55]

TREATMENT

Genital Herpes

The most achievable goals in the management of genital herpes are to relieve symptoms and to shorten the clinical course, to prevent complications and recurrences, and to decrease disease transmission. Although research has focused primarily on the treatment of active infection and suppression of recurrences, increasing emphasis is being placed on various approaches, including immunotherapy that might provide protection from disease transmission or possibly eliminate established latency.[47–48]

Palliative and supportive measures are the cornerstone of therapy for patients with genital herpes. Pain and discomfort usually respond to warm saline baths or the use of analgesics, antipyretics, or antipruritics; good genital hygiene can prevent the development of bacterial superinfection.

4 Specific chemotherapeutic approaches to treating genital herpes include antiviral compounds, topical surfactants, photodynamic dyes, immune modulators, vaccines, and interferons. Few of these have undergone extensive evaluation, however, and only the antiviral agents have demonstrated any consistent clinical efficacy. The most recent CDC recommendations for the treatment of genital herpes include the antiviral agents acyclovir, valacyclovir, and famciclovir[1] (Table 126–10). The overall efficacy of these agents in treating genital HSV infection appears comparable, although patient compliance can be improved with regimens requiring less frequent dosing.[1,43,44]

FIRST-EPISODE INFECTIONS

Oral formulations of acyclovir, famciclovir, and valacyclovir have demonstrated efficacy in reducing viral shedding, duration of symptoms, and time to healing of first-episode genital herpes infections, with maximal benefits seen when therapy is initiated at the earliest stages of infection. Table 126–10 lists the recommended acyclovir, famciclovir, and valacyclovir oral regimens for first-episode infections. In immunocompromised patients or those with severe symptoms or complications necessitating hospitalization, parenteral acyclovir can be beneficial; however, the IV regimen has been associated with renal, gastrointestinal, bone marrow, and CNS toxicity, particularly in patients with renal dysfunction receiving high doses. No antiviral regimen is known to prevent latency or alter the subsequent frequency and severity of recurrences in humans.[1,43–48,51,52,56–59]

TABLE 126-10 Treatment of Genital Herpes

Type of Infection	Recommended Regimens[a,b]	Alternative Regimen
First clinical episode of genital herpes[c]	Acyclovir 400 mg PO 3 times daily for 7–10 days,[d] *or* Acyclovir 200 mg PO 5 times daily for 7–10 days,[d] *or* Famciclovir 250 mg PO 3 times daily for 7–10 days,[d] *or* Valacyclovir 1 g PO twice daily for 7–10 days[d]	Acyclovir 5–10 mg/kg IV every 8 hours for 2–7 days or until clinical improvement occurs, followed by oral therapy to complete at least 10 days of total therapy[e]
Recurrent infection		
Episodic therapy	Acyclovir 400 mg PO 3 times daily for 5 days,[g] *or* Acyclovir 800 mg PO twice daily for 5 days,[g] *or* Acyclovir 800 mg PO 3 times daily for 2 days,[g] *or* Famciclovir 125 mg PO twice daily for 5 days,[g] *or* Famciclovir 1,000 mg PO twice daily for 1 day,[g] *or* Valacyclovir 500 mg PO twice daily for 3 days,[g] *or* Valacyclovir 1 g PO once daily for 5 days[g]	
Suppressive therapy	Acyclovir 400 mg PO twice daily, *or* Famciclovir 250 mg PO twice daily, *or* Valacyclovir 500 mg or 1,000 mg PO once daily[h]	

CDC, Centers for Disease Control and Prevention; HIV, human immunodeficiency virus; PO, orally.
[a]Recommendations are those of the CDC.
[b]HIV-infected patients can require more aggressive therapy.
[c]Primary or nonprimary first episode.
[d]Treatment duration can be extended if healing is incomplete after 10 days.
[e]Only for patients with severe symptoms or complications that necessitate hospitalization.
[f]Recommendations based on studies using this dosage regimen rather than the lower dosage regimens recommended for first clinical episodes of genital herpes. It is not clear whether lower dosage regimens would have comparable efficacy. Famciclovir and valacyclovir are probably also effective for proctitis and oral infection, but clinical experience is limited.
[g]Requires initiation of therapy within 24 hours of lesion onset or during the prodrome that precedes some outbreaks.
[h]Valacyclovir 500 mg appears less effective than valacyclovir 1,000 mg in patients with approximately 10 recurrences per year.

RECURRENT INFECTIONS

There are two approaches to management of recurrent episodes: episodic or chronic suppressive therapy. Episodic therapy is initiated early during the course of the recurrence, preferably within 6 to 12 hours of the onset of prodromal symptoms but no more than 24 hours after the appearance of lesions. In most patients, appreciable effects on symptomatology are not seen. Patients with prolonged episodes of recurrent infection or severe symptomatology are most likely to benefit from episodic therapy. Table 126–10 lists the recommended acyclovir, famciclovir, and valacyclovir suppressive regimens. One concern with episodic therapy is that some patients continue to shed virus despite the absence of lesions or presence of prodromal symptoms. Because of the relative mildness and brevity of recurrent infections, parenteral administration of acyclovir usually is not justifiable.[1,43–48,51,52,56–59]

Suppressive therapy with recommended antivirals reduces the frequency and severity of recurrences in 70% to 80% of patients experiencing frequent recurrences. Asymptomatic viral shedding is markedly reduced in patients receiving suppressive therapy; however, the extent to which this decreases disease transmission

to sexual partners remains to be determined. Despite antiviral suppressive therapy, low-level virus shedding still occurs. However, this virus shedding may be less than that seen in patients treated episodically for recurrences, and thus may be associated with a lower risk of disease transmission. Because the frequency of recurrences tends to diminish over time, periodic "drug holidays" are advocated to assess changes in the underlying recurrence rate and determine if continued suppressive therapy is warranted.[1,43–48,51,52,56–59]

CLINICAL CONTROVERSY

The role of antiviral agents in the treatment of most recurrent genital herpes episodes is controversial. Because signs and symptoms of recurrent infections generally are milder and of shorter duration than those of first-episode infections in immunocompetent hosts, demonstration of clinically important therapeutic benefits is difficult. However, as episodic, asymptomatic viral shedding is common in HSV-2 infection, suppressive therapy in combination with use of condoms provides some protection to uninfected sexual partners.

Resistant HSV isolates have been identified in some patients experiencing breakthrough recurrences while taking acyclovir. Although there is concern about the development of resistant strains with suppressive therapy, clinical trials have found no evidence of cumulative toxicity or significant resistance in patients treated continuously with the recommended antivirals.[43–48]

SELECTED POPULATIONS

Immunocompromised patients are at greatest risk for severe and recurrent HSV infections. Acyclovir, valacyclovir, and famciclovir have been used to prevent reactivation of infection in patients seropositive for HSV who undergo transplantation procedures or induction chemotherapy for acute leukemia. Immunocompromised individuals, such as patients with acquired immunodeficiency syndrome (AIDS), who fail treatment or prophylaxis with recommended antiviral doses frequently demonstrate improved response with higher doses. If resistance is suspected or confirmed with recommended first-line antivirals, foscarnet is usually effective. However, its use is associated with a greater risk of serious adverse effects. Lesional application of an extemporaneous compounded cidofovir (1%) gel or trifluridine ophthalmic solution appears to offer some benefits also.[1,43–48]

The safety of acyclovir, famciclovir, and valacyclovir during pregnancy is not established, although considerable experience with acyclovir in pregnant patients has produced no evidence of teratogenic effects. Because of the high maternal and infant morbidity associated with first-episode primary genital infections or severe recurrent infections at or near term, many clinicians advocate the use of systemic acyclovir as the standard of care in such cases; however, the effectiveness of such therapy is unknown. The use of acyclovir to suppress recurrent episodes near term is more controversial primarily because of the lack of data demonstrating significant benefits in this situation.[1,43–48,60–63]

With the increasing prevalence of genital herpes worldwide, the potential exists for widespread use and misuse of acyclovir, valacyclovir, and famciclovir, resulting in development of resistant HSV isolates. In vitro resistance to these three agents usually is mediated by alterations in viral thymidine kinase; most resistant isolates are either thymidine kinase–deficient or have altered thymidine kinase. The incidence and clinical implications of HSV resistance require further study particularly with respect to immunocompromised hosts, in whom resistance can develop with greater frequency and be of greater clinical importance. Unlike acyclovir, valacyclovir, and famciclovir, foscarnet does not require the presence of thymidine kinase to be effective.[43–48]

Numerous agents for the prophylaxis and treatment of genital herpes infections are being studied. Neither topical nor systemic interferons have demonstrated consistent beneficial effects in genital HSV infections; however, a reduction in pain and time of healing of lesions has been reported with an interferon preparation incorporated into a gel containing nonoxynol-9. Other treatments under investigation include cidofovir and immune modulators such as imiquimod and resiquimod.[43–48] Agents that can eliminate ganglionic latency and prevent recurrent HSV infections are not expected to be available in the near future. Development of vaccines capable of protecting against HSV infection has proved challenging given the relative lack of protection offered by humoral and cell-mediated immunity in preventing naturally occurring recurrent infections. Safety concerns with live attenuated virus vaccines resulted in research focused primarily on recombinant protein vaccines that have exhibited relatively poor immunogenicity. Use of heterologous vaccines (bacillus Calmette-Guérin and influenza vaccines) to stimulate the immune system in patients with recurrent genital herpes has proved of no significant benefit.[43–48,64]

EVALUATION OF THERAPEUTIC OUTCOMES

Available antiviral compounds are of greatest benefit in patients experiencing first-episode primary infections, immunocompromised patients, and patients with frequent or severe recurrent infections. Antivirals, however, are palliative and not curative, and patients receiving these agents should be monitored closely for adverse drug effects. CDC guidelines suggest that discontinuation of suppressive therapy after 1 year should be considered to assess for possible changes in the patient's intrinsic pattern of recurrence. In many patients, decreases in recurrence rates and the severity of symptoms occur over time. However, some clinicians prefer to continue suppressive therapy indefinitely because it significantly reduces asymptomatic viral shedding, a potential benefit in reducing the risk of disease transmission to uninfected sexual partners.[1,43–48]

TRICHOMONIASIS

EPIDEMIOLOGY AND ETIOLOGY

Trichomonas vaginalis, a flagellated, motile protozoan is responsible for 3 to 5 million cases of trichomoniasis annually in the United States. Humans are host to two other *Trichomonas* species, *Trichomonas tenax* and *Trichomonas hominis*, but *T. vaginalis* is the only species thought to be pathogenic. Although infection by nonsexual contact is reported, it is rare. Contamination of inanimate objects and spread of infection via communal bathing or contact with infected bath or toilet articles is possible because *T. vaginalis* can survive for up to 45 minutes on moist surfaces. Neonatal infections also represent another possible nonvenereal route of disease transmission.[65–69]

Coinfection with other STDs is not unusual in patients diagnosed with trichomoniasis. Women infected with *T. vaginalis* are three times more likely to have gonorrhea than those who do not have trichomoniasis; approximately 20% of men with gonococcal urethritis also have trichomoniasis.[65–69] In patients treated appropriately for genital *C. trachomatis* or *U. urealyticum* infection, persistent urethritis can result from coexisting trichomonal infection. Although not well documented, the inflammatory response produced by trichomoniasis may increase the risk of acquiring HIV.[1,65–70]

PATHOPHYSIOLOGY

Trichomonads typically can be isolated from the vagina, urethra, and paraurethral ducts and glands in the majority of infected women. Infrequently, they are recovered from the endocervix. Extragenital sites are epidemiologically important because infection can persist and result in reinfection of the vagina if local therapy alone is used. This may account for the higher relapse rates reported for local versus systemic therapy. After attachment to the vaginal or urethral mucosa, trichomonads usually elicit an inflammatory response that manifests as a discharge containing large numbers of PMN leukocytes.[65–74]

CLINICAL PRESENTATION

Trichomonal infections are reported more commonly in women than in men. In part this might be because of the smaller number of organisms found in the male urethra making detection more difficult, greater disease transmission rates from males to females, and the nature of male infections, which have a high spontaneous cure rate even in the absence of treatment.[66,67,70–72,75] The typical clinical presentation of trichomoniasis in males and females is presented in Table 126–11.

DIAGNOSIS

T. vaginalis produces nonspecific symptoms also consistent with bacterial vaginosis; as a result, laboratory diagnosis is required.

TABLE 126-11 Presentation of *Trichomonas* Infections

	Males	Females
General	Incubation period 3–28 days Organism can be detectable within 48 hours after exposure to infected partner	Incubation period 3–28 days
Site of infection	Most common: urethra Others: rectum (usually caused by rectal intercourse in MSM), oropharynx, eye	Most common: endocervical canal Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	Can be asymptomatic (more common in males than females) or minimally symptomatic Urethral discharge (clear to mucopurulent) Dysuria, pruritus	Can be asymptomatic or minimally symptomatic Scant to copious, typically malodorous vaginal discharge (50%–75%) and pruritus (worse during menses) Dysuria, dyspareunia
Signs	Urethral discharge	Vaginal discharge Vaginal pH 4.5–6 Inflammation/erythema of vulva, vagina, and/or cervix Urethritis
Complications	Epididymitis and chronic prostatitis (uncommon) Male infertility (decreased sperm motility and viability)	Pelvic inflammatory disease and associated complications (i.e., ectopic pregnancy, infertility) Premature labor, premature rupture of membranes, and low–birth-weight infants (risk of neonatal infections is low) Cervical neoplasia

MSM, men who have sex with men.

Because *T. vaginalis* requires a pH range of 4.9 to 7.5 for survival, a vaginal discharge pH of greater than 5.0 usually indicates the presence of either *T. vaginalis* or *Gardnerella vaginalis*, a common cause of bacterial vaginosis. The simplest and most reliable means of diagnosis is a wet-mount examination of the vaginal discharge.[67,70–72,75] Trichomoniasis is confirmed if characteristic pear-shaped, flagellating organisms are observed. The wet mount is only about 60% to 80% sensitive in detecting the presence of trichomonads, with lower sensitivities reported in men and in women with low-grade, subacute, or chronic infections.[68–70,72,74]

Although the presence of trichomonads may be reported on a Papanicolaou (Pap) smear, the sensitivity of this cytologic technique is less than for wet mount and also is associated with a high number of false-positive and false-negative results. Stained smears of cervical specimens have been used in diagnosis, but they are less sensitive and more time consuming than the wet mount and therefore are not recommended. Culture techniques for trichomonads are highly specific and more sensitive than the wet mount, but they are not useful in rapid diagnosis because up to 48 hours or longer is necessary for growth. Cultures can be necessary, however, to confirm the diagnosis in the absence of a positive wet mount or to determine antimicrobial susceptibility in intractable cases.[1,65–72,74,75]

Newer diagnostic tests such as monoclonal antibody or DNA probe techniques, as well as PCR tests that can detect small amounts of trichomonal DNA, have been developed. These office-based tests are highly sensitive and specific for detecting infection in both vaginal specimens and urine. However, these tests are still not widely used.[65–69]

In males, demonstration of trichomonads in urethral specimens or urine sediment by wet mount is difficult, and diagnosis depends largely on culture. Specimens from males should be taken prior to first voiding because the small number of trichomonads in males may be reduced by micturition.[65–71]

TREATMENT

Trichomoniasis

Recommended and alternative treatment regimens for *T. vaginalis* include either metronidazole or tinidazole, both of which produce high cure rates in these infections. In only a few cases have *T. vaginalis* isolates been resistant to standard metronidazole or tinidazole doses. In these instances, longer courses of therapy or doses higher than those recommended routinely as initial therapy usually produce a cure.[1,65–69,72,75,76]

Table 126–12 provides treatment recommendations for trichomonas infections.[1] The standard therapy for trichomoniasis is either metronidazole or tinidazole 2 g orally as a single dose; cure rates are comparable with the recommended alternative regimen of metronidazole 500 mg twice daily for 7 days. When sexual partners are treated simultaneously, cure rates greater than 95% are reported. If sexual partners are not treated concurrently, cure rates are somewhat lower. In limited clinical testing, single metronidazole doses of less than 1.5 g are associated with high failure rates.[1,65–69,72,75,76]

Advantages of single-dose therapy over the multidose alternative regimen include better patient compliance, lower total dose, lower cost, and shorter exposure of the patient's gastrointestinal and urogenital anaerobic bacterial flora to the drug. As a result of the latter, the likelihood of developing pseudomembranous colitis or symptomatic candidal vulvovaginitis is decreased.[65–69,72] Because high doses of metronidazole have mutagenic effects in bacteria and oncogenic effects in mice, a reduced time of exposure in humans can be beneficial. There is no conclusive evidence for either of these

TABLE 126-12 Treatment of Trichomoniasis

Type	Recommended Regimen[a]	Alternative Regimen
Symptomatic and asymptomatic infections	Metronidazole 2 g PO in a single dose[b] *or* Tinidazole 2 g PO in a single dose	Metronidazole 500 mg PO 2 times daily for 7 days[c] *or* Tinidazole 2 g PO in a single dose[d]
Treatment in pregnancy	Metronidazole 2 g PO in a single dose[e]	

CDC, Centers for Disease Control and Prevention; PO, orally.

[a]Recommendations are those of the CDC.

[b]Treatment failures should be treated with metronidazole 500 mg PO twice daily for 7 days. Persistent failures should be managed in consultation with an expert. Metronidazole or tinidazole 2 g PO daily for 5 days has been effective in patients infected with *Trichomonas vaginalis* strains mildly resistant to metronidazole, but experience is limited; higher doses also have been used.

[c]Metronidazole labeling approved by the FDA does not include this regimen. Dosage regimens for treatment of trichomoniasis included in the product labeling are the single 2 g dose; 250 mg 3 times daily for 7 days; and 375 mg twice daily for 7 days. The 250 mg and 375 mg dosage regimens are currently not included in the CDC recommendations.

[d]For treatment failures with metronidazole 2 g as a single dose.

[e]Metronidazole is pregnancy category B and tinidazole is pregnancy category C; both drugs are contraindicated in the first trimester of pregnancy. Some clinicians recommend deferring metronidazole treatment in asymptomatic pregnant women until after 37 weeks gestation.

effects in humans after short-term therapy with recommended doses. Gastrointestinal complaints (e.g., anorexia, nausea, vomiting, and diarrhea) are more common with the single 2-g dose of either metronidazole or tinidazole, occurring in 5% to 10% of treated patients. Some patients also complain of a bitter metallic taste in the mouth with metronidazole. Patients intolerant of the single 2-g dose because of gastrointestinal adverse effects usually tolerate the alternative metronidazole multidose regimen.[65–69,72,75,76]

5 To achieve maximal cure rates and prevent relapse with either metronidazole or tinidazole as a single 2-g dose, simultaneous treatment of infected sexual partners is necessary. In women treated with the alternative 7-day course, however, relapse rates are not appreciably different regardless of whether or not sexual partners are treated. It is speculated that in men, spontaneous resolution of trichomonal infection or a reduction in the number of trichomonads below the inoculum necessary to transmit disease may occur during the 7 days of a female's therapy. In patients who fail to respond to an initial course of metronidazole therapy, a second course of therapy with metronidazole 500 mg twice daily for 7 days or a single 2-g dose of tinidazole is recommended. Patients refractory to a second course of treatment usually respond to a regimen using higher dosages of either agent (i.e., 2–4 g daily for 5–14 days). Good response rates also are reported for metronidazole 2 to 3 g orally plus either a single 500-mg tablet administered intravaginally or intravaginal metronidazole gel (0.75%) for 7 to 14 days.[61,65–69,71,76,77] Topical vaginal therapy alone is associated with low cure rates because infections involving the urethra or periurethral glands are unaffected and can serve as the source of reinfection.[67] Use of intravenous metronidazole can be warranted for rare cases of intolerance to oral medication or infections resistant to high-dose oral metronidazole. Sexual partners of all patients who require retreatment also should be treated or retreated because the majority of apparent treatment failures appear to be caused by reinfection or noncompliance.[65–69]

Concerns regarding the use of metronidazole in women who are pregnant or breast-feeding have been raised. Because metronidazole is secreted in breast milk, it is recommended that breast-feeding be interrupted for 12 to 24 hours after maternal ingestion of a single 2-g dose. Metronidazole (pregnancy category B) and tinidazole (pregnancy category C) are contraindicated during the first trimester of pregnancy based on Food and Drug Administration (FDA)–approved labeling. Although some experts recommend avoiding use of either agent throughout pregnancy, others advocate the use of metronidazole during any stage of pregnancy because of the potential adverse pregnancy outcomes associated with trichomoniasis. Currently no consensus exists on whether or how to treat trichomonas infections in pregnant women.[1,65–69]

Various local therapies for trichomoniasis have been proposed, particularly for pregnant patients. Clotrimazole vaginal suppositories, 100 mg at bedtime for 1 to 2 weeks, relieve symptoms in many women and produce cure rates of 50% or greater. An alternative therapy is gentle douching with either a diluted solution of vinegar or a 1% zinc sulfate solution until symptoms improve and then less frequently thereafter. This therapy generally provides some symptomatic improvement but few cures. Although once recommended, povidone-iodine douches should be avoided during pregnancy because of the risk of fetal thyroid suppression.[65–69]

Several other nitroimidazole antibiotics related to metronidazole and tinidazole (e.g., nimorazole, ornidazole, and carnidazole) are being investigated worldwide for the treatment of trichomoniasis. Unfortunately, none of these agents differs significantly from metronidazole or tinidazole in terms of efficacy (i.e., cross-resistance is high) or toxicity against metronidazole-susceptible strains of *T. vaginalis*.[65–69]

EVALUATION OF THERAPEUTIC OUTCOMES

Follow-up is considered unnecessary in patients who become asymptomatic after treatment with recommended therapy. When patients remain symptomatic, it is important to determine if reinfection has occurred. In these cases, a repeat course of therapy, as well as identification and treatment or retreatment of infected sexual partners, is recommended. In situations in which reinfection can be excluded, a relative resistance to metronidazole or tinidazole should be assumed, and an alternative regimen should be prescribed. Culture and sensitivity are warranted for infections unresponsive to alternative regimens.

HUMAN PAPILLOMAVIRUS AND OTHER STDS

Several STDs other than those just discussed occur with varying frequency in the United States and throughout the world. Although an in-depth discussion of these diseases is beyond the scope of this chapter, Table 126–13 lists recommended treatment regimens.[1] Of notable importance among these other STDs, however, is genital HPV infection, the most common viral STD in the United States. More than 100 HPV types have been characterized by genomic makeup, with approximately 30 types associated with genital tract lesions.[79–81] Of these, types 6 and 11 are associated most commonly with the development of low-grade dysplasia manifested as exophytic genital warts. In most individuals, genital infection with HPV is subclinical, and patients with visible acuminate warts represent less than 1% of all infected individuals. When present, genital warts can be large and multifocal, producing variable degrees of discomfort. Based on HPV DNA detection methods, most warts will regress spontaneously within 1 to 2 years of their initial appearance. However, reinfection is common in young, sexually active populations.[1,78,79]

Infection with several HPV types, particularly HPV-16 and HPV-18, is considered the major risk factor for the development

TABLE 126-13 Treatment Regimens for Miscellaneous Sexually Transmitted Diseases

Infection	Recommended Regimen[a]	Alternative Regimen
Chancroid (*Haemophilus ducreyi*)	Azithromycin 1 g PO in a single dose, *or* Ceftriaxone 250 mg IM in a single dose, *or* Ciprofloxacin 500 mg PO twice daily for 3 days,[b] *or* Erythromycin base 500 mg PO 4 times daily for 7 days	
Lymphogranuloma venereum	Doxycycline 100 mg PO twice daily for 21 days[c]	Erythromycin base 500 mg PO 4 times daily for 21 days
Human papillomavirus (HPV) infection		
External genital warts	*Provider-Administered Therapies:* Cryotherapy (e.g., liquid nitrogen or cryoprobe), *or* Podophyllin resin 10%–25% in compound tincture of benzoin applied to lesions; repeat weekly if necessary,[d,e] *or* Trichloroacetic acid 80%–90% *or* Bichloracetic acid 80%–90% applied to warts; repeat weekly if necessary, *or* Surgical removal (tangential scissor excision, tangential shave excision, curettage, or electrosurgery) *Patient-Applied Therapies:* Podofilox 0.5% solution or gel applied twice daily for 3 days, followed by 4 days of no therapy; cycle is repeated as necessary for up to four cycles,[e] or Imiquimod 5% cream applied at bedtime 3 times weekly for up to 16 weeks[e]	Intralesional interferon or laser surgery
Vaginal and anal warts	Cryotherapy with liquid nitrogen, or TCA or BCA 80%–90% as for external HPV warts; repeat weekly as necessary[f] Surgical removal (not for vaginal or urethral meatus warts)	
Urethral meatus warts	Cryotherapy with liquid nitrogen, or podophyllin resin 10%–25% in compound tincture of benzoin applied at weekly intervals[e,g]	

[a]Recommendations are those of the Centers for Disease Control and Prevention (CDC).
[b]Ciprofloxacin is contraindicated for pregnant and lactating women and for persons aged <18 years.
[c]Azithromycin 1 g PO once weekly for 3 weeks can be effective.
[d]Some experts recommended washing podophyllin off after 1–4 hours to minimize local irritation.
[e]Safety during pregnancy is not established.
[f]Surgical removal of anal warts is also a recommended treatment.
[g]Some specialists recommend the use of podofilox and imiquimod for treating distal meatal warts.

of cervical neoplasia, the second most common cancer in women worldwide. Although epidemiologic, virologic, and clinical data strongly support this association, HPV infection alone is insufficient to cause cervical cancer development because only a small percentage of infected women develop the disease. It appears that the interplay of host immune defenses, genetic factors, and infection with HPV types containing a more aggressive variant all contribute to the risk of developing cervical neoplasia.[78,79]

The Pap smear is the most cost-effective and frequently used diagnostic test for HPV. It can detect abnormal cytology in patients with clinical manifestations and those with subclinical disease (i.e., no overt condylomata) but not latent HPV infection. Visual inspection of genital surfaces under magnification can assist in making the diagnosis. Various tests for detecting HPV DNA also are available, and unlike the Pap smear do not require subjective interpretation of the results. Currently HPV DNA testing is only approved in women with abnormal Pap smears or women older than 30 years of age. However, use of HPV DNA testing as a routine screening test in lieu of Pap smears is expected in the near future. In women identified to have high-risk HPV infections by these tests, follow-up cytology would be performed.[78,79]

No consensus exists on the best approach to treating patients with genital HPV infection, particularly because most cases appear to be transient with spontaneous regression of lesions. A number of treatments are recommended (see Table 126–13), but none is clearly superior to the others. Treatment generally is directed toward patients with manifestations of genital warts, with the goal of removing or destroying these lesions and grossly infected surrounding tissue. Because such treatment neither stops viral expression in surrounding tissue nor eliminates viral latency, recurrence of lesions is not uncommon.[78,79]

Two HPV vaccines are marketed in the United States. Cervarix, a bivalent vaccine for HPV-16 and -18, and Gardasil, a quadrivalent vaccine for HPV-6, -11, -16, and -18. Both vaccines are indicated for preventing cervical precancers and cervical cancer in females 9 to 26 years of age. In addition, Gardasil is indicated for the prevention of genital warts caused by HPV-16 and -18 in males between the ages of 9 and 25 years. Clinically important differences in the magnitude and duration of the immune response, as well as prevention of HPV infections and cervical cancer remain to be determined.[80–83]

ABBREVIATIONS

AIDS: acquired immunodeficiency syndrome
CDC: Centers for Disease Control and Prevention
CSF: cerebrospinal fluid
DFA-TP: direct fluorescent-antibody test
DGI: disseminated gonorrhea infection
EIA: enzyme immunoassay
FDA: Food and Drug Administration
FTA-ABS: fluorescent treponemal antibody absorption
HIV: human immunodeficiency virus
HPV: human papillomavirus
HSV: herpes simplex virus
HSV-1: herpes simplex virus type 1
LPS: lipopolysaccharide
MHA-TP: microhemagglutination assay for antibodies to *T. pallidum*

MSM: men who have sex with men

NAATs: nucleic acid amplification tests

NGU: nongonococcal urethritis

Pap: Papanicolaou smear

PCR: polymerase chain reaction

PID: pelvic inflammatory disease

PMN: polymorphonuclear

QRNG: quinolone-resistant *N. gonorrhoeae*

RPR: rapid plasma reagin

STD: sexually transmitted disease

TPHA: *T. pallidum* hemagglutination assay

TPPA: *T. pallidum* particle agglutination assay

TRUST: toluidine red unheated serum test

USR: unheated serum reagin

VDRL: Venereal Disease Research Laboratory

CHAPTER 127

Bone and Joint Infections

EDWARD P. ARMSTRONG AND ALLAN D. FRIEDMAN

KEY CONCEPTS

1. The most common cause of osteomyelitis (particularly that acquired by hematogenous spread) and infectious arthritis is *Staphylococcus aureus*.
2. Culture and susceptibility information are essential as a guide for antimicrobial treatment of osteomyelitis and infectious arthritis.
3. Joint aspiration and examination of synovial fluid are extremely important to evaluate the possibility of infectious arthritis.
4. The most important treatment modality of acute osteomyelitis is the administration of appropriate antibiotics in adequate doses for a sufficient length of time.
5. Antibiotics generally are given in high doses so that adequate antimicrobial concentrations are reached within infected bone and joints.
6. The standard duration of antimicrobial treatment for acute osteomyelitis is 4 to 6 weeks.
7. Oral antimicrobial therapy can be used for osteomyelitis to complete a parenteral regimen in children who have had a good clinical response to intravenous (IV) antibiotics and in adults without diabetes mellitus or peripheral vascular disease when the organism is susceptible to the oral antimicrobial, a suitable oral agent is available, and compliance is ensured.
8. The three most important therapeutic maneuvers in the management of infectious arthritis are appropriate antibiotics, joint drainage, and joint rest.
9. Monitoring of antibiotic therapy is important and typically involves noting clinical signs of inflammation, periodic white blood cell counts, C-reactive protein (or erythrocyte sedimentation rate) determinations, and radiographic findings.

Bone and joint infections are composed of two disease processes known, respectively, as *osteomyelitis* and *septic* or *infectious arthritis*. They are unique and separate infectious entities with different signs and symptoms and infecting organisms. Despite advances in therapy, these infections continue to cause significant morbidity from residual damage and chronic recurring infections. Emphasis on initiating antibiotic therapy as soon as possible is important in reducing long-term complications.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

Osteomyelitis generally is an uncommon disease. One classic publication reported that 247 patients had osteomyelitis in a prominent American teaching hospital during a 4-year period.[1] Acute osteomyelitis has an estimated annual incidence of 0.4 per 1,000 children.[2] Osteomyelitis caused by contiguous spread, including postoperative, direct puncture, and that associated with adjacent soft tissue infections, comprises 47% of infections. Hematogenous osteomyelitis comprises 19% of infections, and osteomyelitis occurring in patients with significant peripheral vascular disease comprises 34% of infections. A review of osteomyelitis cases based on duration of disease shows that acute disease constitutes 56% of patients and that chronic osteomyelitis, defined as having a previous hospitalization for the same infection, constitutes 44% of patients.

Infectious or septic arthritis is an inflammatory reaction within the joint space. Distinct from osteomyelitis, septic arthritis is a more common disease and is one of the most common causes of new cases of arthritis. One study identified 22 patients with culture-proven septic arthritis at a tertiary teaching hospital over 10 years.[3] Another hospital reported 15 cases of neonatal septic arthritis of the hip in a 3-year period.[4] Overall, the yearly incidence of bacterial arthritis varies from 2 to 10 per 100,000 inhabitants.[5]

ETIOLOGY

OSTEOMYELITIS

The most common method of classifying osteomyelitis is based on the route in which the infecting organism reaches the bone. Infection that results from spread through the bloodstream is termed *hematogenous osteomyelitis*. When the organism reaches the bone from an adjoining soft tissue infection, it is termed *contiguous osteomyelitis*. Osteomyelitis that results from direct inoculation, such as from trauma, puncture wounds, or surgery, generally is also classified under the contiguous osteomyelitis category. Patients with peripheral vascular disease are at risk for the development of osteomyelitis, and these patients often are separated into a third distinct category because of their unique management features. Osteomyelitis also can be classified based on the duration of the disease. Acute osteomyelitis describes infections of recent onset, usually several days to 1 week, whereas chronic infections are those of a longer duration. Some authors describe chronic infections as those with symptoms for more than 1 month before therapy, whereas

TABLE 127-1 Types of Osteomyelitis, Age Distribution, Common Sites, and Risk Factors

Type of Osteomyelitis	Typical Age (years)	Site(s) Involved	Risk Factors
Hematogenous	Younger than 1	Long bones and joints	Prematurity, umbilical catheter or venous cutdown, respiratory distress syndrome, perinatal asphyxia
	1–20	Long bones (femur, tibia, humerus)	Infection (pharyngitis, cellulitis, respiratory infections), trauma, sickle cell disease, puncture wounds to feet
	Older than 50	Vertebrae	Diabetes mellitus, blunt trauma to spine, urinary tract infection
Contiguous	Older than 50	Femur, tibia, mandible	Hip fractures, open fractures
Vascular insufficiency	Older than 50	Feet, toes	Diabetes mellitus, peripheral vascular disease, pressure sores

other authors define chronic infections as relapse of an initial infection. Yet a third system sometimes used to classify osteomyelitis is based on the anatomic location of the infection (medullary or superficial) and the physiologic status of the patient (otherwise healthy, systemic immunologic compromise, or local immunologic compromise).[6,7] This classification system can be useful when comparing patients among different studies and attempting to categorize the severity of infection.

INFECTIOUS ARTHRITIS

Infectious arthritis can occur from many different types of microorganisms.[8] Most infecting organisms are known to produce an infection in a single joint, termed *monarthritic infections*; however, infections also can involve two or more joints.[9] As with osteomyelitis, joint infections can be classified according to the mechanisms by which the infecting organism reaches the joint. Infectious arthritis can result from the spread of an adjacent bone infection, direct contamination of the joint space, or hematogenous dissemination. Hematogenous spread of the disease comprises the majority of infections; spread from osteomyelitis and direct inoculation are much less frequent.[10] Infectious arthritis occurs most commonly in patients older than age 16 years; however, approximately one-fourth of cases occur in children 15 years or younger.[11]

PATHOPHYSIOLOGY

HEMATOGENOUS OSTEOMYELITIS

Hematogenous osteomyelitis is described classically as a disease of children because most cases occur in patients younger than 16 years of age.[7] Table 127–1 summarizes the primary characteristics of osteomyelitis. Less commonly, these infections occur in adults. One exception, vertebral osteomyelitis, involves the vertebrae and occurs most frequently in patients older than 50 years.

Unique features of the anatomy and physiology of some bones appear to predispose them to become infected.[12] The vascular structure within the long bones appears to predispose the bone for hematogenous infections to begin within the metaphyses (Fig. 127–1). The nutrient arteries of the long bones divide within the medullary canal of the bone into small arterioles. These end in hairpin turns near the growth plate and flow into veins, of much wider diameter, that drain the medullary cavity.[1] An infection in hematogenous disease is initiated within the bend of the arterioles. There is considerable slowing of blood flow passing through the hairpin turns within the arterioles and then into the wider venous structures. This sludging of blood flow allows bacteria present within the bloodstream to settle and initiate an inflammatory response. In addition to these structural features, there appears to be less active phagocytosis within the metaphysis. After the bacteria settle in the bone, avascular necrosis can occur from occlusion of the nutrient vessels and release of bacterial enzymes.

In addition to these anatomic and functional features, there is some evidence that trauma is associated with developing an infection in specific bones. Children who develop hematogenous osteomyelitis may report some type of trauma as an etiologic event. Animal data also indicate that traumatized bone is more likely to become infected than normal bone.

Once the infection is initiated, exudate begins to form within the bone, which produces increased pressure. The age of the patient largely determines the next stage in the pathophysiology. In children older than 12 to 18 months, the infection that started in the metaphysis of a long bone is prevented from spreading into the joint because of the growth plate; however, the exudate often expands laterally through the thin outer cortex of the bone and raises the loose periosteum. The periosteum is thick and not easily broken, and the resulting pus usually remains subperiosteal. If there is significant periosteal damage, a soft tissue abscess can develop. Impairment of blood flow to the outer portion of the cortical bone can occur, producing dead bone that separates from healthy bone, termed *sequestra*. The elevated periosteum remains viable because its blood supply, derived from the overlying muscle, is unaffected. The raised periosteum will continue to produce bone; however, this new bone is now separated from the cortex because the periosteum has been raised from the infection. This new bone is termed *involucrum*.

In adults, the periosteum is tightly bound, and the cortex is thick. These anatomic features generally cause the infections to remain intramedullary. As expected, subperiosteal abscess formations are less common in this population. The infection can spread to adjacent bone structures through the haversian and Volkmann canals.

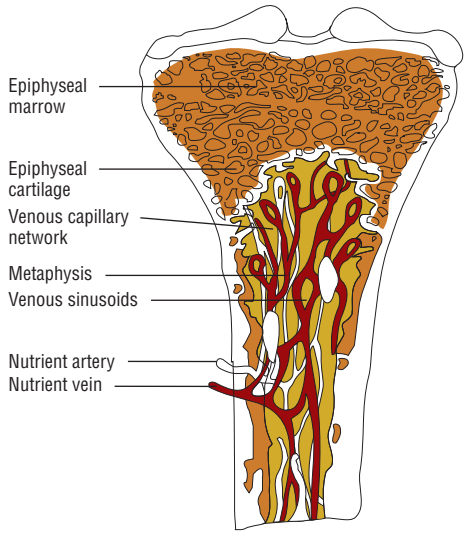

FIGURE 127-1. Cross section of normal bone.

Chronic osteomyelitis is more likely to occur if large segments of bone become avascular and necrotic.

Neonatal patients also have unique characteristics, blood vessels that spread through the cortex of the metaphyses and up into the epiphyses. This enables an infection that started within the metaphyseal area to spread easily to involve the epiphyses and then into the joint.[13] Therefore, in infants, not only can the infection spread to involve the periosteum and the shaft as in children, but the infection also can spread to involve the joint.[14]

Hematogenous osteomyelitis also is known to have a predilection for certain bones, depending on the age of the patient. Children most commonly develop infections within the femur, tibia, humerus, and fibula.[14] Vertebral infections are more common in patients older than 50 years.[15] Neonatal infections commonly involve multiple bones.

1 The bacteriology of hematogenous osteomyelitis is unique compared with osteomyelitis caused by other routes of infection. A single organism is responsible for the vast majority of hematogenous infections. *Staphylococcus aureus* is isolated most frequently with hematogenous infections in children. In immunocompetent children who have been fully vaccinated with the *Haemophilus influenzae* type B vaccine, this is now an uncommon pathogen causing bone and joint infections.[16] However, neonatal osteomyelitis has a wider spectrum of infecting organisms. The three most common etiologic agents are *S. aureus,* group B streptococcus, and *Escherichia coli.* The infections from *S. aureus* and *E. coli* have been linked to complications occurring during pregnancy or delivery, and they are involved most frequently in multiple-bone infections.

Vertebral osteomyelitis has several unique features and occurs most commonly in adults 50 to 60 years of age. The lumbar and thoracic regions are the locations of most infections. Hematogenous infections are most likely to develop in the vascular areas near the subchondral plate region of the vertebral body. Staphylococci cause ~60% of these infections; however, gram-negative organisms now play a significant role. These gram-negative organisms, particularly *E. coli,* most likely originate within the urinary tract. *E. coli* vertebral infections have been associated with urinary tract infections, positive urine cultures, and bacteremias. *Mycobacterium tuberculosis* also is known to cause infections in the spine. Skin and respiratory tract infections are other foci of infections known to lead to vertebral infections.

A unique category of osteomyelitis patients consists of individuals with a history of IV drug abuse. More than 50% of the osteomyelitis infections in this group of patients are found in the vertebral column. Less than 20% of infections are located in either the sternoarticular or pelvic girdle. Infections are much less frequent within the extremities. An unusual feature of osteomyelitis in the IV drug-abusing population is the spectrum of organisms. Gram-negative organisms are responsible for 88% of infections. *Pseudomonas aeruginosa,* either singly or in combination with other organisms, is cultured in 78% of all infections. *Klebsiella, Enterobacter,* and *Serratia* species also can be found but less commonly. In addition, staphylococcal and streptococcal organisms are sometimes cultured.

Patients with sickle cell anemia and related hemoglobinopathies have a much higher rate of infection with *Salmonella* species as compared with other populations.[17] *Salmonella* species are responsible for two-thirds of the infections in these patients. Bowel infarctions from the sickle cell disease can facilitate salmonellae entry into the bloodstream from the colon and spread hematogenously to the bone. Osteomyelitis in patients with sickle cell disease may occur in any bone, but it is observed to be most common in the medullary cavity of long or tubular bones. Because of the difficulty in separating bone pain during a sickle cell crisis from that of an infection, osteomyelitis can be relatively advanced in these patients when the diagnosis is made. Although salmonellae are cultured most frequently, staphylococci and other gram-negative organisms also can be isolated.

CONTIGUOUS-SPREAD OSTEOMYELITIS

This category of osteomyelitis includes infections caused by direct entrance of organisms from a source outside the body or progressive spread of an infection from tissue adjacent to the bone. Penetrating wounds (e.g., trauma), open fractures, and various invasive orthopedic procedures can result in direct inoculation of organisms into the bone. Infections also can occur secondary to pressure ulcers. More than 80% of cases of postoperative osteomyelitis are known to occur following open reductions of fractures. Specifically, these infections occur most commonly after internal fixation of a hip fracture or femoral or tibial shaft fracture.

Osteomyelitis secondary to an adjoining soft tissue infection comprises another very important group of contiguous infections and most often involves the fingers and toes. Less commonly, infections can spread from infected teeth to involve the mandible or occur secondary to sinus infections by spreading through the mucosal lining of the sinuses into the vascular system surrounding the bone.[18,19]

In contrast to hematogenous osteomyelitis, which occurs most commonly in children, contiguous-spread osteomyelitis occurs most commonly in patients older than age 50. Most likely this is so because important predisposing factors, such as hip fractures, are more common in this age group.

Contiguous-spread disease has several important differences compared with hematogenous osteomyelitis. Although *S. aureus* is still the most common organism isolated, infections with multiple organisms, including gram-negative bacilli, occur frequently. *P. aeruginosa,* streptococcus, *E. coli, Staphylococcus epidermidis,* and anaerobes all can be isolated. One important exception to this wide range of organisms is puncture wounds of the feet. There is a correlation between puncture wounds of the feet and gram-negative osteomyelitis (sometimes classified as osteochondritis), especially infections caused by *P. aeruginosa.*

Patients with osteomyelitis in association with severe vascular insufficiency are extremely difficult to manage.[20,21] As anticipated, most of these patients have diabetes mellitus or severe atherosclerosis, and they develop their infections from contiguous-spread mechanisms. Generally, these patients are between the ages of 50 and 70 years when they develop osteomyelitis. Frequently, patients with vascular disease develop osteomyelitis in their toes and fingers, and there is usually an adjacent area of infection, such as cellulitis or dermal ulcers.

Another important characteristic of osteomyelitis in association with vascular insufficiency is the spectrum of infecting organisms. Infections in these patients almost always include multiple organisms. The mixed-flora infections often include staphylococcus and streptococcus or the combination of staphylococcus, streptococcus, and Enterobacteriaceae. Enterococci and anaerobic organisms also can be involved.

Anaerobic organisms also play a role in osteomyelitis. When anaerobes are grown from cultures, they usually are found in association with other organisms, including aerobic bacteria. Predisposing factors in patients who have anaerobic osteomyelitis include vascular disease, bites, contiguous infections, peripheral neuropathy, hematogenous spread, and trauma.[22] The anaerobic infections in association with diabetes mellitus almost always occur within the feet. *Bacteroides fragilis* and *Bacteroides melaninogenicus* comprise the majority of anaerobic isolates.

INFECTIOUS ARTHRITIS

Distinct from osteomyelitis, infectious arthritis usually is acquired by hematogenous spread.[9] The synovial tissue is highly vascular and does not have a basement membrane, so organisms in the blood

TABLE 127-2 Characteristics of Acute Infectious Arthritis

Feature	Finding
Peak incidence	Children younger than 16 years Adults older than 50 years
Clinical findings	Fever of 38–40°C (100.4–104°F) in children; painful swollen joint in the absence of trauma Physical examination: effusion, restriction of joint motion, tenderness, and warmth of joint
Most commonly affected joints	Knee, hip, ankle, elbow, wrist, and shoulder
Laboratory findings:	
Erythrocyte sedimentation rate	Elevated in 90% of cases
White blood cell count	Elevated in 30–60% of cases
Left shift	Seen in two-thirds of patients
Blood culture	Positive in 40% of cases
Needle aspiration of joint	Gram stain diagnostic in 30–50% of cases. Synovial fluid cultures are positive in 60–80% of cases. Synovial fluid differential reveals 90% polymorphonuclear leukocytes. Synovial fluid glucose decreased relative to serum glucose. Lactic acid levels elevated in nongonococcal infectious arthritis but not in gonococcal infectious arthritis

can easily reach the synovial fluid. Table 127–2 summarizes the characteristics of acute infectious arthritis. Some organisms, such as *Neisseria gonorrhoeae,* are especially likely to infect a joint during bacteremia. In addition, organisms can gain access to the joint from a deep-penetrating wound, an intraarticular steroid injection, arthroscopy, prosthetic joint surgery, and contiguous osteomyelitis expansion into the joint.[3]

The risk factors associated with adult infectious arthritis (more than one factor may be present) are systemic corticosteroid use, preexisting arthritis, arthrocentesis, distant infection, diabetes mellitus, trauma, and other diseases.[23]

Trauma also appears to be a risk factor in facilitating microorganism entry into the synovial space. One study found that 35% of patients with infectious arthritis had preexisting joint disease.[11] Unlike children, adults often have significant systemic diseases that predispose them to infectious arthritis, such as diabetes mellitus, immunosuppressive states (e.g., cancer and liver disease), and preexisting arthritis. IV drug abusers also are prone to develop septic arthritis.

Arthritis, joint trauma, and surgery are other important risk factors because chronic inflammation or trauma makes the joint more susceptible to infection. In addition, patients with rheumatoid arthritis can be prone to bacterial infection because of an inherent phagocytic defect, as well as concomitant corticosteroid therapy. Hormonal factors appear to play a role in *N. gonorrhoeae* infectious arthritis. Women are more prone to develop disseminated gonococcal infections than men. The second and third trimesters of pregnancy and during menstruation appear to be the times of greatest risk for developing gonococcal bacteremia.

After bacteria gain access to the joint, the organisms begin to multiply and produce a persistent purulent effusion within the joint. If this joint effusion is present beyond 7 days, chronic, and sometimes irreversible, damage can occur. Purulent effusions can promote cartilage destruction by increasing leukocyte enzyme activity. In conjunction with the development of the effusion, almost all patients will develop a hot, swollen, painful joint. The proteolytic enzymes within the effusion and pressure necrosis can lead to cartilage and bone damage.

1 *S. aureus,* the single most common infecting organism, is found in 48% of cases of nongonococcal bacterial arthritis. Streptococcal infections account for 18% of cases, and gram-negative organisms are less common.[11] Overall, *E. coli* is the most common of the gram-negative organisms; however, *P. aeruginosa* is the most frequent organism in IV drug abusers. Neonates may have infectious arthritis because of a broad range of organisms, with *S. aureus,* streptococcus, and gram-negative organisms being most common. *S. aureus* and streptococcus are the most common pathogens in children younger than 5 years. If the child has not been fully vaccinated or is immunocompromised, *H. influenzae* type B may be a cause. Within the adult population, *S. aureus* is responsible for the vast majority of nongonococcal infections. The most common cause of bacterial arthritis in adults 18 to 30 years of age is *N. gonorrhoeae,* which are the most common infections in women.[24] Patients with a terminal complement deficiency (C5–C9) are at increased risk of disseminated infections with *Neisseria* species. Although less common, nonbacterial causes of osteomyelitis and septic arthritis include fungi and viruses.[25]

TABLE 127-3 Clinical Presentation of Hematogenous Osteomyelitis

Signs and symptoms
Significant tenderness of the affected area, pain, swelling, fever, chills, decreased motion, and malaise
Laboratory tests
Elevated erythrocyte sedimentation rate, C-reactive protein, and white blood cell count. Fifty percent of patients will have positive blood cultures.
Diagnostic studies
Bone changes observed on radiographs 10–14 days after the onset of infection. Technetium and gallium scans are positive as early as 1 day after the onset of infection.

CLINICAL PRESENTATION

The clinical presentation of acute hematogenous osteomyelitis is summarized in Table 127–3. Although neonatal hematogenous osteomyelitis can spread rapidly to involve the joint, often there are few systemic symptoms present. A joint effusion is present in 60% to 70% of neonatal infections. Decreased limb motion and edema over the affected area may be the only signs from which to make a diagnosis. Pyogenic vertebral osteomyelitis produces nonspecific symptoms, such as severe back pain, fever or night sweats, and weight loss. The pain typically is present at rest and increases in severity with movement. Neurologic symptoms can occur if the infection extends and compresses the spinal cord. With contiguous-spread osteomyelitis, there is often an area of localized tenderness, warmth, edema, and erythema over the infected site. Patients with significant vascular insufficiency usually have local symptoms, such as pain, swelling, and redness. Less commonly, patients with vascular disease also can have a fever and elevated white blood cell (WBC) count. The presentation of osteomyelitis from surgery or trauma depends on the precipitating cause. If the infection follows surgery or bone trauma, the symptoms usually are noted within 1 month. The most frequent symptom is simply pain in the area of infection. Less commonly, patients also can develop a fever and elevated WBC count.

Patients with nongonococcal bacterial arthritis almost always present with a fever, and 50% of patients have an elevated WBC count (see Table 127–2). The average initial synovial WBC count is $10 \times 10^3/mm^3$ or greater in nongonococcal bacterial disease. The most frequent initial sign of disseminated gonococcal infections is a migratory polyarthralgia. In addition, two-thirds of patients complain of fever, dermatitis, and tenosynovitis (inflammation of the tendon sheath).

Nongonococcal bacterial arthritis almost always involves only a single joint. The knee is the most commonly involved joint, but

infections also can occur in the shoulder, wrist, hip, ankle, interphalangeal joints, and elbow joints. Usually, the initial focus of infection that acted as the source for bacterial or microbial entrance can be identified. Common routes for bacterial entrance are infections of the respiratory tract, skin, and urinary tract. Blood cultures are important in these patients because they can be positive in 50% of patients.

Another type of infectious arthritis occurs following prosthetic joint surgery. With these infections, the erythrocyte sedimentation rate (ESR) usually is elevated, although a leukocytosis often is absent. Infections that result from postoperative contamination usually become apparent within 1 year of surgery.

RADIOLOGIC AND LABORATORY TESTS

The evaluation of a patient who may have osteomyelitis has several unusual aspects. Radiographs of the involved area should be obtained; however, bone changes characteristic of osteomyelitis are not seen for at least 10 to 14 days after the onset of the infection. Radiologists may note soft tissue swelling before any bone changes become obvious. Bone lesions do not appear on roentgenogram films until 10 days after infection because >50% of the bone matrix must be removed before the lesions can be detected. To aid in improving the diagnosis, magnetic resonance imaging (MRI) and bone scanning are commonly used.[26,27]

Despite the seriousness of osteomyelitis, often there are few laboratory abnormalities. The ESR, C-reactive protein, and WBC count may be the only laboratory abnormalities.[14] The degree of abnormality of these laboratory findings does not correlate with the disease outcome; however, they are useful for monitoring therapy. C-reactive protein can be elevated because of the presence of inflammation, and it can be substituted for the ESR. It is generally the more sensitive and specific marker of response to therapy and often increases and decreases before the ESR.

When a clinical assessment of osteomyelitis is suspected, it is important to establish a bacteriologic diagnosis by culture of the infected bone. Accurate culture information is especially important as a guide for treatment of osteomyelitis. Bone aspiration is valuable in determining an accurate bacteriologic diagnosis. In addition, performing a bone aspiration determines whether or not there is an abscess present. If an abscess is located, the pus is cultured, and a Gram stain is performed. If an abscess is found, the fluid needs to be drained and cultured. Aspirates of subperiosteal pus or metaphyseal fluid yield a pathogen in 70% of cases. Cultures should be done for both aerobic and anaerobic bacteria. A Gram stain of the aspirate can be useful in initiating empirical antibiotic therapy. This allows a more appropriate choice of antibiotics from the first day of therapy rather than waiting several days while culture results are pending.

If a specimen is obtained from a previously undrained or unopened wound abscess, the pathogen usually can be identified. In chronic osteomyelitis, however, identification can be more difficult.[28] Open wounds and draining sinuses frequently are contaminated with other organisms and thus provide inaccurate culture information. Therefore, because of the inaccuracies with sinus tract cultures, they cannot be relied on to reflect the pathogen. Cultures of loculated pus aspirates in the area of orthopedic devices removed from infected bone can be trusted, however, to identify the infecting organism. The preferable time to obtain culture material in a patient with a chronic draining sinus is at the time of open surgical débridement.

2 In addition to performing cultures from the involved bone, it is important to obtain blood cultures from any site believed to be the source of a bacteremia. Approximately 50% of patients with hematogenous osteomyelitis will have positive blood cultures.

3 When evaluating the possibility of a patient having infectious arthritis, immediate joint aspiration with subsequent analysis of the synovial fluid is extremely important. The presence of purulent fluid usually indicates the presence of a septic joint. The synovial fluid WBC count is usually 50 to 200 $\times$ 10^3/mm^3 when an infection is present. Approximately half the patients with an infected joint have a low synovial glucose level, usually <40 mg/dL. Gram stains of joint fluid demonstrate bacteria in 50% of patients with septic arthritis; however, such stains can be positive in only 25% of patients with gonococcal arthritis infections. Synovial fluid cultures usually are positive in patients with nongonococcal infections. Both blood and joint fluid should be cultured aerobically and anaerobically in a patient suspected of having an infected joint. Blood cultures are positive in half of patients with nongonococcal infections but in only 20% of those with gonococcal infections. Pharyngeal, rectal, cervical, or urethral smears and cultures, as well as cultures of cutaneous lesions, should be performed if a disseminated gonococcal infection is considered. As with osteomyelitis, most patients will have an elevated C-reactive protein concentration and ESR. Radiographs of infected joints often reveal distention of the joint capsule with soft tissue swelling in the adjacent space. MRI can be helpful in identifying an infected hip. In patients who have developed an infected prosthetic joint, loosening of the prosthesis can be seen radiographically.

TREATMENT

DESIRED OUTCOME

The goals of treatment are resolution of the infection and prevention of long-term sequelae. The ultimate outcome of osteomyelitis depends on the acute or chronic nature of the disease and how rapidly appropriate therapy is initiated. Patients with acute osteomyelitis have the best prognosis. Cure rates exceeding 80% can be expected for patients with acute osteomyelitis who have surgery as indicated and receive appropriate injectable antibiotics for 4 to 6 weeks. In contrast, patients with chronic osteomyelitis have a much poorer prognosis. Dead bone and other necrotic material from the infection act as a bacterial reservoir and make the infection very difficult to eliminate. Adequate surgical debridement to remove all the dead bone and necrotic material, combined with prolonged administration of antibiotics, provides the best chance to obtain a cure. The inability to remove all the dead bone can allow residual infection and require suppressive antibiotics to control the infection.

In comparison, many patients who develop infectious arthritis recover with no long-term sequelae. Gonococcal arthritis usually resolves rapidly with antibiotics; however, patients with staphylococcal arthritis have a higher incidence of joint damage. Individuals at greatest risk for long-term sequelae are those who have symptoms present for more than 7 days before starting therapy and those with infections occurring within the hip joint and infections caused by gram-negative organisms. Common long-term residual effects following infectious arthritis are limited joint motion and persistent pain. Shortening of the affected extremity is another well-known complication. More than half the children in one hospital who subsequently developed residual joint damage were believed normal at the time of hospital discharge.

GENERAL APPROACH TO TREATMENT

4 Following completion of the steps needed to determine the infecting organism, the most important treatment modality of acute osteomyelitis is the administration of appropriate antibiotics in adequate doses for a sufficient length of time. It is important to stress

that early antibiotic therapy can mitigate the need for surgery.[29] A delay in treatment can allow bone necrosis to occur and make eradication of the infection much more difficult. In these patients, recurrent exacerbations of the infection can result if all necrotic tissue is not removed surgically and all microorganisms eliminated. Adjunctive treatment with hyperbaric oxygen or antibiotic-impregnated implants during surgery also has been used.[30,31]

If a patient with hematogenous osteomyelitis does not respond by having a decrease in fever, local swelling, redness, and pain following the initiation of adequate antibiotic therapy, the patient should undergo surgical debridement of the infected area. It is important to emphasize the priority of starting antibiotics immediately after the cultures have been obtained. No treatment failures have been reported when injectable antibiotics were started within 48 hours of the onset of symptoms in children with osteomyelitis.

PHARMACOLOGIC THERAPY

Antibiotic Bone Concentration

5 Antibiotics used in the management of acute osteomyelitis generally are given in high doses (adjusted for weight and renal and/or hepatic function) so that adequate antimicrobial concentrations are reached within the infected bone and joint.[32] Between 8 and 12 g/day of a penicillinase-resistant penicillin (nafcillin or oxacillin), ampicillin, or cephalosporin or a similar large dose of another parenteral antibiotic is used in the initial management of adults with osteomyelitis. These dosing recommendations, however, are empirical; the relationship between a specific dose of a given antibiotic and its resulting concentration within the infected bone is largely unknown. Semisynthetic penicillins, cephalosporins, clindamycin, and the aminoglycosides can be detected in bone homogenates soon after their administration.

Daptomycin may also be an effective empiric therapy for the treatment of osteomyelitis in adults.[33] It is effective against most methicillin-sensitive and -resistant *S. aureus*. Although a retrospective study, these results support the use of daptomycin, especially when other standard therapies have failed. Further prospective studies are needed to define the situations in which daptomycin might be best used and its optimal dosing.

CLINICAL CONTROVERSY

Some clinicians recommend coverage empirically for methicillin-resistant *Staphylococcus aureus* (MRSA) when staphylococcal infection is suspected. Others believe that culture results and sensitivity testing or lack of response to routine staphylococcal antibiotics should trigger use of antibiotics directed against MRSA. The frequency of MRSA in a community may help govern which approach is used.

Duration of Antibiotic Therapy

6 The specific duration of antibiotic therapy needed in the management of osteomyelitis is usually 4 to 6 weeks.[34] Failure rates approaching 20% have been observed in children treated with injectable antibiotics for 3 weeks or less. Thus, with the data indicating a minimum of 3 weeks of antibiotic therapy, the standard treatment for osteomyelitis has been parenteral antibiotics for 4 to 6 weeks.[35] Although these data were largely evaluated in children, this duration-of-therapy recommendation is also used in adults.[36] Treatment failures may be due to the presence of infected necrotic bone or infected hardware (wires, plates, screws, and rods) that could not be removed.

A modification of this recommendation has been used in some patients. Children receiving an appropriate oral antibiotic regimen and adults receiving an oral fluoroquinolone antibiotic, such as ciprofloxacin, for a duration of 6 weeks have been treated successfully. Monitoring the patient's clinical signs and symptoms and the C-reactive protein level or ESR is an important parameter to assess therapy. If signs or symptoms are still present at 6 weeks, therapy should be extended. In contrast, children who have had a puncture wound of the foot resulting in *P. aeruginosa* osteochondritis and who have had surgical debridement of infected material can be treated with parenteral antibiotics for 10 days.

Oral Antibiotic Therapy

7 One of the most significant changes in the management of osteomyelitis is the use of oral antibiotics to complete therapy.[37] Criteria for the use of oral outpatient antibiotic therapy for osteomyelitis include the following:

- Confirmed osteomyelitis
- Initial clinical response to parenteral antibiotics
- Suitable oral agent available
- Compliance ensured

Suitable candidates are children with good clinical response to IV therapy and adults without diabetes mellitus or peripheral vascular disease.

Two primary populations have benefited from oral treatment. Children responding to initial parenteral therapy may be excellent candidates to receive follow-up oral therapy with an agent such as dicloxacillin, cephalexin, or amoxicillin, depending on their culture and sensitivity results.[38] Although more controversial, the other population to benefit from oral therapy is adults with an infecting organism sensitive to a fluoroquinolone.[39] These two populations now no longer routinely require expensive and complicated courses of long-term parenteral antibiotics.

The use of oral antibiotics is well studied in children.[40] Several studies documenting the effectiveness of oral therapy used injectable antibiotics initially, then switched to oral antibiotics when there was a decrease in the signs of inflammation and the ESR or when the patient was afebrile for 3 days.[38] If pus was obtained on the initial needle aspirate, or if a reduction in fever, local swelling, and tenderness did not occur despite adequate rest, immobilization, and intensive antibiotic therapy, the patients underwent surgical drainage.

The patients enrolled in oral antibiotic trials generally had disease of recent onset, identification of a specific infecting organism, enforced compliance, and surgery as indicated. In patients who meet these criteria, oral antibiotics appear to offer a great advantage in the treatment of osteomyelitis.[41] Patients not meeting these criteria are more likely to develop chronic osteomyelitis with resulting recurrent exacerbations of the infection if oral therapy is attempted. Limited retrospective data in adults indicated that parenteral therapy for less than 4 weeks followed by oral therapy may be effective.[42]

Ciprofloxacin is effective in the treatment of osteomyelitis caused by gram-negative strains, such as *Enterobacter cloacae* and *Serratia marcescens*;[43] however, many strains of streptococci are relatively resistant. Activity of ciprofloxacin against gram-negative bacilli allows patients to be treated orally and avoids the potential toxic complications of 4 to 6 weeks of aminoglycoside therapy. Ciprofloxacin and other fluoroquinolones also have demonstrated effectiveness in the treatment of chronic osteomyelitis along with

adequate surgical debridement.[44,45] Another benefit with this agent is that it can be administered on an every-12-hour schedule. An important limitation of this antibiotic class, however, is that fluoroquinolones should not be used in children younger than 16 to 18 years of age or in pregnant women because of the potential to cause cartilage damage. Other limitations of ciprofloxacin are that it has poor coverage against anaerobic organisms and staphylococci and that *P. aeruginosa* can develop resistance. Newer fluoroquinolones have additional gram-positive activity; however, additional well-controlled clinical trials are needed to determine most appropriately their role in the treatment of osteomyelitis.[46]

Concern has been raised about staphylococci resistance to fluoroquinolones. Methicillin-resistant *S. aureus* infections do not respond well to ciprofloxacin; however, resistance also can be troublesome for methicillin-sensitive strains. It is now recommended that when ciprofloxacin is to be used to treat osteomyelitis with mixed etiologies that include *S. aureus,* it should be combined with an antistaphylococcal drug such as dicloxacillin, cephalexin, or clindamycin.

CLINICAL CONTROVERSY

Some clinicians believe that oral fluoroquinolones should be preferred treatments for osteomyelitis, whereas others believe that there have been inadequate studies to date to determine their comparative clinical effectiveness.

Antibiotic Selection

A critical component in the management of osteomyelitis is the selection of appropriate antibiotics. Empirical therapy must be selected on the basis of the most likely infecting organism while the results of culture and sensitivity data are pending. Table 127–4 summarizes empirical therapy recommendations. It is difficult to make evidence-based recommendations on the treatment of these infections, as little high-quality clinical evidence exists. Experimental evidence, case series, and published expert opinion are used to suggest preferred treatment options.[29] Dosages expressed in terms of milligrams per kilograms per day generally are given in divided doses every 6 to 8 hours (three or four times a day).

Because *S. aureus,* streptococci, and *E. coli* are the most common infecting organisms in newborns, an IV dosage of 150 mg/kg/day (given in four divided doses) of oxacillin or nafcillin plus cefotaxime 150 mg/kg/day (given in three or four divided doses) is appropriate. For children 5 years of age or younger, *S. aureus* and streptococci are the most common infecting organisms. Appropriate therapy in this age group is an IV dosage of nafcillin or oxacillin 150 mg/kg/day or cefazolin 100 mg/kg/day. If the patient is immunocompromised or has not been fully vaccinated, empirical therapy is needed to also cover *H. influenzae* type B. In this setting, IV dosage of cefuroxime 150 mg/kg/day is appropriate empirical therapy. For children older than 5 years, *S. aureus* is the most likely infecting organism, and either nafcillin 150 to 200 mg/kg/day IV or cefazolin 100 mg/kg/day IV is recommended. If patients are allergic to penicillins or cephalosporins or are infected with MRSA, vancomycin, clindamycin, or linezolid can be used.[47–49] Children with culture-negative osteomyelitis can be managed as presumed staphylococcal disease with excellent long-term results.[50] Empiric therapy may need to be modified if community-acquired methicillin-resistant *S. aureus* is prevalent.[51] Children with osteomyelitis usually can be treated successfully with 4 weeks of parenteral therapy or parenteral followed by oral therapy.

An oral regimen can be an alternative to the previous recommendation in many cases of osteomyelitis in children. Children who have undergone surgery, if needed, and have had a good clinical response to IV therapy may be candidates for the alternate oral antibiotic regimen. Parenteral antibiotic therapy should be initiated and continued until there has been a resolution in the erythema, swelling, and tenderness and until the patient is afebrile. Dicloxacillin, cloxacillin, and cephalexin (100 mg/kg/day) are effective oral agents. Patients should be monitored with periodic WBC counts, C-reactive protein (or ESR) determinations, and radiographic findings. When oral antibiotics are used, the total duration of oral and injectable therapy is usually at least 4 to 6 weeks. As stated previously, because of the risk of cartilage damage, fluoroquinolones should not be used in children. Hematogenous osteomyelitis in adults is caused most frequently by *S. aureus* and thus is treated appropriately with 8 to 12 g/day of a penicillinase-resistant penicillin, such as nafcillin. A similar dose of a first-generation cephalosporin (e.g., cefazolin), clindamycin 2.4 g/day, or vancomycin 2 g/day (with normal renal function) can be used in adults allergic to penicillin. If the infection

TABLE 127-4 Empirical Treatment of Osteomyelitis

Patient Subtype	Likely Infecting Organism	Antibiotic[a]	Recommendation Grades[b]
Newborn	*Staphylococcus aureus,* streptococci, *Escherichia coli*	Nafcillin or oxacillin 50–150 mg/kg/day IV plus cefotaxime 100–200 mg/kg/day IV	B–3
Children 5 years of age or younger	If vaccinated for *Haemophilus influenzae* type B: *S. aureus* or streptococci	Nafcillin 150 mg/kg/day IV or cefazolin 100 mg/kg/day IV	B–3
	If not vaccinated against *H. influenzae* type B	Cefuroxime 150 mg/kg/day IV	B–3
Children older than 5 years of age	*S. aureus*	Nafcillin 150 mg/kg/day IV or cefazolin 100 mg/kg/day IV	A–3
Adults	*S. aureus*	Nafcillin 2 g IV every 4 hours or cefazolin 2 g IV every 8 hours	A–3
IV drug abusers	*Pseudomonas*	Ciprofloxacin 750 mg PO twice daily or ceftazidime 2 g IV every 8 hours plus tobramycin 5 mg/kg/day IV	B–3
Postoperative or posttrauma patients	Gram-positive and gram-negative organisms	Nafcillin 2 g IV every 4 hours plus ceftazidime 2 g IV every 8 hours or ticarcillin-clavulanate 3.1 g IV every 4 hours	B–3
Patients with vascular insufficiency	Gram-positive and gram-negative organisms	Nafcillin 2 g IV every 4 hours or cefazolin 2 g IV every 8 hours plus ceftazidime 2 g IV every 8 hours	B–3
	If anaerobes suspected	Cefotetan 2 g IV every 12 hours or clindamycin 900 mg IV every 8 hours plus ceftazidime 2 g IV every 8 hours	C–3

[a]Dosage should be adjusted for some agents in patients with renal and/or hepatic dysfunction.
[b]Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1 = Evidence from more than one properly randomized, controlled trial. 2 = Evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments. 3 = Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities. PO = orally.

is located within the vertebrae, *E. coli* must be considered; thus, depending on the culture and sensitivity data, a switch to a cephalosporin may be needed.[52] After institution of appropriate antibiotic therapy, the antimicrobial agent should be continued for at least 4 to 6 weeks total (parenteral plus oral).

CLINICAL CONTROVERSY

Some clinicians believe that empirical therapy of osteomyelitis and septic arthritis in a child younger than 5 years of age no longer requires *H. influenzae* type B coverage, whereas others are concerned about children not being fully vaccinated and desire to use an antibiotic with activity against this organism.

Special Populations Osteomyelitis in a patient with a hemoglobinopathy, such as sickle cell anemia, is commonly caused by either *Salmonella* or *S. aureus*.[17] Thus, empirical antibiotics of first choice are ceftriaxone and cefotaxime. Alternatives are chloramphenicol and ciprofloxacin (in adults). Bone infections in adults with a history of IV drug abuse require coverage for gram-negative organisms; therefore, empirical treatment with ceftazidime 2 g IV every 8 hours plus an aminoglycoside is indicated. If compliance can be ensured, these patients are excellent candidates to receive oral ciprofloxacin 750 mg twice daily. Antibiotic therapy in these patients should be continued for at least 4 to 6 weeks.

As discussed previously, several microorganisms can cause bone infections that occur after surgery or from contiguous spread of an adjacent soft tissue infection. *S. aureus* is the single most common organism, but multiple organisms can be involved. To provide the required broad-spectrum coverage, nafcillin 2 g IV every 4 hours plus ceftazidime 2 g intravenously every 8 hours should be used as initial therapy. An alternative single agent is ticarcillin–clavulanate potassium 3.1 g IV every 4 hours in adults; however, there is less experience with this agent. Other broad-spectrum alternatives can be cefepime and imipenem. The antibiotic regimen can require modification after culture and sensitivity information is evaluated. Based on the culture and sensitivity data, ciprofloxacin can be an appropriate oral alternative for these patients. Frequently, the antibiotics must be continued for 6 weeks to obtain a cure, and surgery often is required to remove any infected or devitalized tissue.

Patients with established vascular insufficiency who subsequently develop osteomyelitis are extremely difficult to manage.[6] Impaired blood flow to the extremities impedes the healing process, possibly requiring vascular bypass surgery.[53] Infections in these patients involve a wide range of organisms, including *S. aureus, Streptococcus,* anaerobes, and gram-negative organisms. Bone culture–based antibiotic therapy has been associated with cure in diabetics with osteomyelitis of the foot.[54] Broad-spectrum therapy with a penicillinase-resistant penicillin in combination with ceftazidime is the preferred initial therapy. If anaerobes are suspected, an antianaerobic cephalosporin (e.g., cefoxitin) or clindamycin plus ceftazidime can be substituted. Ampicillin may need to be added to the regimen to provide coverage against enterococci. Despite aggressive antibiotic therapy along with surgical debridement, these patients continue to have low cure rates.[55,56] Amputation of the involved area may be required to obtain a cure of the infection.[57,58]

Home Antibiotic Therapy Because the management of bone and joint infections frequently requires prolonged parenteral antibiotics, newer antibiotic regimens have been used. Administration of antibiotics in the home environment and use of antibiotics with extended elimination half-lives are possible. Although acute osteomyelitis is one of the more common infectious diseases that can be treated with home IV antibiotics, not all patients are acceptable candidates for home administration.[59] Patients must be screened to include only those who are receiving a stable treatment program, those who are interested and are motivated in participating, and those who have good venous access, as well as those who have support from family members or neighbors and have home facilities for storage and refrigeration. Patients with adequate vascular access may be able to use a peripheral IV catheter; however, a central IV catheter may be required if venous access difficulties occur. Certain exclusion criteria also must be considered. Complications of other preexisting diseases, such as diabetic retinopathy, intention tremor, disabling inflammation or degenerative joint disease, coagulopathies, or various neurologic disorders can prevent individuals from receiving home antibiotics. A history of alcoholism or of IV drug abuse also is an important exclusion criterion. Patients who are fluent only in a foreign language and those who are illiterate or hard of hearing may have to be excluded if a qualified guardian is unavailable. In addition to meeting these initial screening criteria, patients must complete a thorough training program successfully before hospital discharge. Aseptic technique, proper catheter care, and correct administration techniques must be documented. Once a patient is receiving therapy in the home environment, continued monitoring of his or her antimicrobial therapy is important. It is vital to ensure compliance with the antimicrobial regimen. Catheter-related complications are common in patients receiving prolonged courses of parenteral antibiotics.[60]

In addition, the specific antibiotic regimen characteristics must be considered when evaluating a patient for home antibiotics.[61] Some important features are microbiologic culture and sensitivity data, the number of required daily antimicrobial doses, antibiotic stability data, and requirements for unique monitoring for the specific antimicrobial regimen, such as serum creatinine and peak and trough concentration measurements with aminoglycosides. Although an organism can be sensitive to several antimicrobial agents, one antibiotic can provide practical benefits over other agents. Patients who have an infecting organism that is sensitive to one of the longer-acting (less frequently dosed) cephalosporins and is resistant to less expensive agents (cefazolin) may benefit from the newer antibiotics. It is important, however, to monitor for the development of resistant strains and superinfections.

Infectious Arthritis 8 The three most important therapeutic maneuvers in the management of infectious arthritis are appropriate antibiotics, joint drainage, and joint rest. Smears of the synovial fluid can be useful to select appropriate antibiotic therapy initially.[62] If bacteria are not observed on the Gram stain in a patient who has a purulent joint effusion, antibiotics still should be initiated because of the high risk of an infection being present.[63] A delay in initiating antibiotics significantly increases the likelihood for long-term complications.[64,65]

The specific antibiotic selected depends on the most likely infecting organism.[66] In infants younger than 1 month, the infecting organisms vary widely, and empirical therapy thus must provide broad-spectrum coverage. A penicillinase-resistant penicillin such as nafcillin or oxacillin plus an aminoglycoside is appropriate. Children younger than 5 years who have been immunized for *H. influenzae* type B should receive nafcillin, oxacillin, or cefazolin.

In children older than 5 years and in adults, initial therapy with a penicillinase-resistant penicillin is appropriate to provide the

necessary coverage against *S. aureus*. Therapy should be changed to clindamycin, vancomycin, or linezolid if the *S. aureus* is resistant to methicillin.[67,68] Preliminary data indicate that children with infectious arthritis can be converted to oral therapy after initial IV therapy.[69] As with osteomyelitis, IV drug abusers require coverage for *P. aeruginosa*; therefore, combination therapy with an aminoglycoside is needed. The antibiotics selected usually are administered parenterally. Antibiotics administered by this route achieve sufficient concentrations within the synovial fluid; thus, intraarticular antibiotic injections are unnecessary. Although studies to define clearly the appropriate length of therapy have not been conducted, 2 to 3 weeks of antibiotic therapy generally is adequate in nongonococcal infections. Less than 2 weeks of therapy combined with one joint aspiration was effective in closely monitored children with infectious arthritis.[70,71] Joint fluid cultures usually are no longer positive after 7 days of antibiotics.

Disseminated gonococcal infections often respond quickly to antibiotics.[72] Ceftriaxone 1 g/day for 7 to 10 days is the treatment of choice for adults. After culture and sensitivity results are available, and the organism is determined to be sensitive, therapy can be switched on the fourth day to oral amoxicillin or to doxycycline or tetracycline to complete the 7- to 10-day course. Clinical resolution of signs and symptoms usually is rapid.

Closed-needle aspiration is recommended for all infected joints except the hip.[72,73] Joint drainage can be repeated daily for 5 to 7 days until effusions no longer reaccumulate. Open drainage is required in hip infections because closed-needle aspiration is difficult and inadequate. During the initial phase of the infection, weight bearing, such as walking, on the joint should be avoided. Passive range-of-motion exercises should be initiated when the pain begins to subside to maintain joint mobility.[74] Approximately one-third of patients with bacterial arthritis have a poor joint outcome, such as severe functional deterioration. Poor joint outcomes are associated with older patients, those with preexisting joint disease, and patients with an infected joint containing synthetic material. Treatment guidelines are useful with septic arthritis of the hip.[75,76]

PHARMACOECONOMIC CONSIDERATIONS

Cost and outcome issues are important in osteomyelitis and infectious arthritis. If long-term sequelae develop, such as impaired joint motion or draining sinus tracts, or if amputation is required, patient quality of life can be significantly diminished. Cost and quality-of-life issues have clearly played a major role in evaluating other treatment alternatives (oral therapy or home antibiotic treatment) rather than requiring patients to remain hospitalized to receive 4 to 6 weeks of parenteral antibiotics. In addition, adverse events commonly occur with prolonged outpatient parenteral antibiotic therapy. One study in 45 children noted that 85.7% of patients receiving vancomycin had adverse drug events, and 42.9% of patients required the drug be discontinued.[77] This analysis also noted that cefazolin had the lowest rate of adverse drug events in this population.

EVALUATION OF THERAPEUTIC OUTCOMES

9 Patients with bone and joint infections must be monitored closely. Table 127–5 summarizes a pharmaceutical care monitoring protocol. An assessment of a therapy's success or failure is based on the patient's clinical findings and laboratory values. The clinical signs of inflammation, such as swelling, tenderness, pain, redness, and fever, should resolve with appropriate therapy. Initially, the clinical signs are assessed daily until improvement, then periodically thereafter. Elevations in WBC count also should decline gradually. The ESR usually is determined weekly. Elevations in the C-reactive protein or ESR may not return to normal for several weeks of therapy. The WBC count usually is obtained once or twice per week until it returns to the normal range. If by the end of the 4- to 6-week antibiotic course the clinical findings of osteomyelitis are no longer present, and the C-reactive protein or ESR is within normal limits, the patient can be considered a clinical cure. Patients can relapse, however, after initially appearing to be cured. No relapse for 1 year generally is considered a complete cure.

TABLE 127-5 Monitoring Protocol

Parameter	Frequency	Notes
Culture and sensitivity	At initiation of treatment	
White blood cell count	One time per week until within normal range	
C-reactive protein or ESR	Weekly	May not decrease to normal range until several weeks of therapy
Clinical signs of inflammation (redness, pain, swelling, tenderness, fever)	Daily during initiation of therapy	
Compliance of outpatient therapy	Reinforce before starting oral therapy and with each healthcare visit	Compliance is critical if treatment is to be successful

ESR = erythrocyte sedimentation rate.

If a patient fails to resolve the clinical signs and symptoms of inflammation after appropriate empirical antibiotics, surgical debridement may be needed. In addition, the patient might have a resistant infecting organism or an atypical infecting organism that can require a modification of the antibiotic therapy. It is especially important to note the infecting organism and its sensitivity pattern. Follow-up cultures at subsequent debridements can be useful to assess the antibiotic therapy.

Despite apparently adequate surgery and antibiotics, some patients can fail therapy and have recurrent relapses in their infection. This scenario is more common in the population with chronic osteomyelitis. These patients can require long-term oral antibiotics to keep the infection under control.

ABBREVIATIONS

ESR: Erythrocyte sedimentation rate

MRSA: Methicillin-resistant *Staphylococcus aureus*

WBC: White blood cell

CHAPTER 128 Severe Sepsis and Septic Shock

S. LENA KANG-BIRKEN AND KARLA KILLGORE-SMITH

KEY CONCEPTS

1. The spectrum of microorganisms associated with sepsis has changed from predominantly gram-negative bacteria in the late 1970s and 1980s to gram-positive bacteria as the major pathogens since the 1990s.
2. Candidemia is a major cause of morbidity and mortality. *Candida albicans* remains the most common pathogen (45.6%); however, non–*C. albicans Candida* species collectively is more frequently isolated (54.4%).
3. Sepsis presents a complex pathophysiology, characterized by the activation of multiple overlapping and interacting cascades leading to systemic inflammation, a procoagulant state, and decreased fibrinolysis.
4. Mortality rates with sepsis are higher for patients with preexisting disease, intensive care unit care, and multiple organ failure.
5. Prompt initiation of broad-spectrum, parenteral antibiotic therapy is required due to the high incidence of complications and mortality with sepsis.
6. A significant volume of fluid leaks from the vasculature occurs with sepsis, and initial fluid resuscitation with large volumes of fluid is required. There is no clinical outcome difference between colloid and crystalloid fluid resuscitation.
7. Norepinephrine is generally preferred over dopamine as the vasopressor to correct hypotension in septic shock. Low-dose dopamine does not maintain or improve renal function.
8. Early goal-directed therapy of sepsis, consisting of hemodynamic monitoring with a central venous catheter, volume resuscitation, inotropic therapy, and red blood cell transfusions, demonstrated a significant clinical outcome benefit with a 16% absolute reduction in 28-day mortality.
9. A blood glucose level less than150 mg/dL is recommended for the majority of critically ill patients to reduce morbidity and mortality without the detrimental effects associated with hypoglycemia.
10. IV hydrocortisone is recommended for adult patients with septic shock whose blood pressure is unresponsive to fluids and vasopressors.
11. Drotrecogin (recombinant human activated protein C), which has both antiinflammatory and anticoagulant properties, was associated with a 6.1% reduction in 28-day all-cause mortality in comparison to placebo and should be used in patients at high risk of death.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Severe sepsis and septic shock continue to pose major healthcare problems. More than 750,000 cases of sepsis occur each year in the United States, and slightly more than half of the patients are admitted to the intensive care unit (ICU) with a mean length of stay of 15.7 days.[1] Despite aggressive medial care and advances, overall mortality from severe sepsis or septic shock ranges from 30% to 60%.[1] Septic shock is the 10th leading cause of death.[2] With the annual cost of approximately $16.7 billion, there is a vital need for clinicians to comprehend the pathophysiology and to appreciate the management options available for acutely ill patients with severe sepsis or septic shock.[1]

DEFINITIONS

In 1992, a joint committee of the American College of Chest Physicians and the Society of Critical Care Medicine standardized the terminology related to sepsis for several reasons: (a) widespread confusion with the use of these terms, (b) the need to provide a flexible classification scheme for patient identification, (c) identification of an earlier therapeutic intervention, and (d) standardization of research protocols.[3]

The criteria for the new terms provide specific physiologic variables that can be used to categorize a patient as having bacteremia, systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, septic shock, or multiple-organ dysfunction syndrome (MODS), suggesting an important continuum of progressive physiologic decline (Table 128–1). Introduction of the term *SIRS* reflects the knowledge that a physiologically similar systemic inflammatory response can be seen even in the absence of identifiable infection (Fig. 128–1).[4] More recently, the classification of sepsis was modified to include severe sepsis, septic shock, and refractory septic shock.[5] *Severe sepsis* refers to patients with an acute organ dysfunction, such as acute renal failure or respiratory failure. *Septic shock* refers to sepsis patients with arterial hypotension that is refractory to adequate fluid resuscitation, thus requiring vasopressor administration. It is important to note that progression from sepsis to MODS can occur in the absence of an intervening period of septic shock. Finally, *refractory septic shock* exists if dopamine IV infusion greater than 15 mcg/kg/min or norepinephrine greater than 0.25 mcg/kg/min is required to maintain a mean blood pressure greater than 60 mm Hg.[5]

TABLE 128-1 Definitions Related to Sepsis

Condition	Definition
Bacteremia (fungemia)	Presence of viable bacteria (fungi) in the bloodstream
Infection	Inflammatory response to invasion of normally sterile host tissue by the microorganisms
Systemic inflammatory response syndrome (SIRS)	Systemic inflammatory response to a variety of clinical insults, which can be infectious or noninfectious. The response is manifested by two or more of the following conditions: temperature >38°C or <36°C; HR >90 beats/min; RR >20 breaths/min or $PaCO_2$ <32 torr; WBC >12,000 cells/mm³, <4,000 cells/mm³, or >10% immature (band) forms; positive fluid balance (>20 mL/kg over 24 h); hyperglycemia; plasma C-reactive protein/procalcitonin >2 SD above normal value; arterial hypotension; CI >3.5 L/min; arterial hypoxemia; acute oliguria; creatinine increase >0.5 mg/dL; coagulation abnormalities; ileus, platelets <100,000 mcL; bilirubin >4 mg/dL; hyperlactatemia; decreased capillary refill
Sepsis	SIRS secondary to infection
Severe sepsis	Sepsis associated with one or more organ dysfunctions, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, and acute alteration in mental status
Septic shock	Sepsis with persistent hypotension despite fluid resuscitation, along with the presence of perfusion abnormalities. Patients who are on inotropic or vasopressor agents may not be hypotensive at the time perfusion abnormalities are measured
Refractory septic shock	Persistent septic shock, requiring dopamine >15 mcg/kg/min or norephinephrine >0.25 mcg/kg/min to maintain mean arterial blood pressure
Multiple organ dysfunction syndrome (MODS)	Presence of altered organ function requiring intervention to maintain homeostasis

CI = cardiac index, HR = heart rate, RR = respiratory rate, SD = standard deviation, T = temperature, WBC = white blood cell (count).

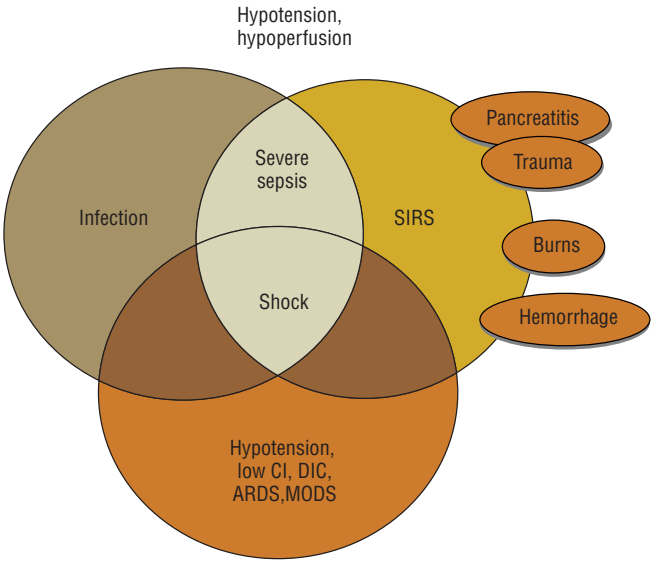

FIGURE 128-1. Relationship of infection, systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, and septic shock. ARDS, acute respiratory distress syndrome; CI, cardiac index; DIC, disseminated intravascular coagulation; MODS, multiple-organ dysfunction syndrome.

INFECTION SITES AND PATHOGENS

Predisposing factors of septic shock include age, male gender, nonwhite ethnic origin in North Americans, comorbid diseases, malignancy, immunodeficiency or immunocompromised state, chronic organ failure, alcohol dependence, and genetic factors.[1,6]

The leading primary sites of microbiologically documented infections that led to sepsis were the respiratory tract (21%–68%), intraabdominal space (14%–22%), and urinary tract (14%–18%).[5,7–9] Although almost any microorganism can be associated with sepsis and septic shock, the most common etiologic pathogens are gram-positive bacteria (40% of patients), followed by gram-negative bacteria (38%) and fungi (17%).[5] Certain viruses and rickettsiae can produce a similar syndrome.

GRAM-POSITIVE BACTERIAL SEPSIS

1 Since 1987, gram-positive organisms have been the predominant pathogens in sepsis and septic shock, accounting for approximately 40% to 50% of all cases.[1] They are commonly caused by *Staphylococcus aureus, Streptococcus pneumoniae*, coagulase-negative staphylococci, and *Enterococcus* species. *Streptococcus pyogenes* and viridans streptococci are less commonly involved.[5,8–11]

S. pneumoniae sepsis is associated with an overall mortality rate of >25%. Factors related to a higher mortality include shock, respiratory insufficiency, preexisting renal failure, and the presence of a rapidly fatal underlying disease. *Staphylococcus epidermidis* is most often related to infected intravascular devices, such as artificial heart valves and stents and the use of IV and intraarterial catheters. The rates of nosocomial enterococcal bacteremia and associated sepsis are also increasing. Enterococci are isolated most commonly in blood cultures following a prolonged hospitalization and treatment with broad-spectrum cephalosporins.

GRAM-NEGATIVE BACTERIAL SEPSIS

A greater proportion of patients with gram-negative bacteremia develop clinical sepsis, and gram-negative bacteria are also more likely to produce septic shock in comparison to gram-positive organisms, 50% versus 25%, respectively.[8,11,12] Gram-negative sepsis also results in a higher mortality rate compared with sepsis from any other group of organisms.[12] The major factor associated with the outcome of gram-negative sepsis appears to be the severity of any underlying condition. Patients with rapidly fatal conditions, such as acute leukemia, aplastic anemia, and burn injury to >70% of the body's surface, have a significantly worse prognosis than do those patients with nonfatal underlying conditions, such as diabetes mellitus and chronic renal insufficiency.[1,2,12]

Escherichia coli and *Pseudomonas aeruginosa* are the most commonly isolated gram-negative microorganisms in sepsis.[5,7–12] Other common gram-negative pathogens are *Klebsiella* species, *Serratia* species, *Enterobacter* species, and *Proteus* species. *P. aeruginosa,* although not considered predominant in human endogenous flora, is found widely in the environment and is the most frequent cause of sepsis fatality. In a European study evaluating sepsis occurring in acutely ill patients, *P. aeruginosa* was isolated from 14% of all cultures.[5]

ANAEROBIC AND MISCELLANEOUS BACTERIAL SEPSIS

Anaerobic bacteria are usually considered low-risk organisms for the development of sepsis. If present, anaerobes are often found together with other pathogenic bacteria that are commonly found in sepsis. Polymicrobial infections accounted for 5% to 39% of

sepsis.[1,5,7–9,12] Mortality rates associated with polymicrobial infections are similar to sepsis caused by a single organism. Although some clinicians believe the particular combination of organisms present in polymicrobial sepsis can provide clues to the source of infection, no clear source for the infection can be identified in up to 25% of cases. Other less common pathogens are meningococcus, gonococcus, rickettsia, chlamydia, and spirochetes.

FUNGAL SEPSIS

2 Candidemia is among the most common etiologic agents of bloodstream infections. Although *C. albicans* was the most commonly isolated fungus from blood cultures (45.6%), collectively, non–*C. albicans Candida* species were more frequently isolated (54.4%).[13] Non-*Candida* species include *C. glabrata* (26%), *C. parapsilosis* (15.7%), *C. tropicalis* (8.1%), and *C. krusei* (2.5%). Other fungi identified as causes of sepsis are Cryptococcus, Coccidioides, Fusarium, and Aspergillus. Risk factors for fungal infection include abdominal surgery, poorly controlled diabetes mellitus, prolonged granulocytopenia, broad-spectrum antibiotic treatment, corticosteroid treatment, prolonged hospitalization, central venous catheter, total parenteral nutrition, hematologic malignancy, and chronic, indwelling bladder (Foley) catheter.

In a prospective analysis of the Antifungal Therapy Alliance database, the overall crude 12-week mortality rate for sepsis due to candidemia was 35.2%.[13] The highest mortality rate of 52.9% was observed in patients with *C. krusei* candidemia; *C. parapsilosis* candidemia was associated with the lowest 12-week mortality rate (23.7%). Hematologic diseases, neutropenia, and a higher number of positive blood cultures were associated with poor outcome irrespective of the patient's gender, age, or days of antifungal drug treatment.

PATHOPHYSIOLOGY

Sepsis is the result of complex interactions among the invading pathogen, the host immune system, and the inflammatory responses. Proinflammatory mediators that contribute to eradication of invading microorganisms are produced, and antiinflammatory mediators control this response. The inflammatory response leads to damage to host tissue, and the antiinflammatory response causes leukocytes to activate. Once the balance to control the local inflammatory process to eradicate the invading pathogens is lost, systemic inflammatory response occurs, converting the infection to sepsis, severe sepsis, or septic shock.[14]

CELLULAR COMPONENTS FOR INITIATING THE INFLAMMATORY PROCESS

The pathophysiologic focus of gram-negative sepsis has been on the lipopolysaccharide component of the gram-negative bacterial cell wall. Commonly referred to as endotoxin, this substance is unique to the outer membrane of the gram-negative cell wall and is generally released with bacterial lysis. Lipid A, the innermost region of the lipopolysaccharide, is highly immunoreactive and is considered responsible for most of the toxic effects observed with gram-negative sepsis. Although lipid A can affect tissues directly, its predominant effect is to activate macrophages and trigger inflammatory cascades critical in the progression to sepsis and septic shock.[14] Endotoxin forms a complex with an endogenous protein called a lipopolysaccharide-binding protein, which then engages the CD14 receptor on the surface of a macrophage. Subsequently, cytokine mediators are activated and released by the macrophage.

In gram-positive sepsis, the exotoxin peptidoglycan appears to exhibit proinflammatory activity. Peptidoglycan comprises up to 40% of a gram-positive cell mass and is exposed on the cell wall surface. Although it competes with lipid A for similar binding sites on CD14, the potency of peptidoglycan is less than that of endotoxin.[14] However, an important feature of gram-positive bacteria such as *S. aureus* and *S. pyogenes* is the production of potent exotoxins, some of which have been associated with septic shock.

PRO- AND ANTIINFLAMMATORY MEDIATORS

Sepsis involves activation of inflammatory pathways, and a complex interaction between proinflammatory and antiinflammatory mediators plays a major role in the pathogenesis of sepsis. The key proinflammatory mediators are tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), and interleukin-6 (IL-6), which are released by activated macrophages.[14–16] Other mediators that may be important for the pathogenesis of sepsis are interleukin-8 (IL-8), platelet-activating factor (PAF), leukotrienes, and thromboxane A_2.

The TNF-α is considered the primary mediator of sepsis.[15,16] Although the TNF-α levels in plasma can be increased in patients with a variety of diseases and in many healthy people, there is a correlation of plasma TNF-α levels with the severity of sepsis. The plasma TNF-α level is highly elevated early in the inflammatory response in most patients with sepsis.[17] In meningococcemia, increased morbidity and mortality are associated with high plasma concentrations of TNF-α. The TNF-α release leads to activation of other cytokines (IL-1 and IL-6) associated with cellular damage. In addition, TNF-α stimulates the release of cyclooxygenase-derived arachidonic acid metabolites (thromboxane A_2 and prostaglandins) that contribute to vascular endothelial damage.

Although IL-1 serum levels have been inconsistently associated with sepsis, IL-6 is a more consistent predictor of sepsis, as it remains elevated for a longer period of time than TNF-α.[15] The highest circulating levels of IL-6 in addition to IL-8 have been associated with severity and mortality.[15,18,19]

The significant antiinflammatory mediators include interleukin-1 receptor antagonist (IL-1RA), interleukin-4 (IL-4), and interleukin-10 (IL-10).[14–16] These antiinflammatory cytokines inhibit the production of the proinflammatory cytokines and downregulate some inflammatory cells. Levels of IL-10 and IL-1RA are higher in septic shock than in sepsis, and higher levels are found among nonsurviving patients than in survivors.[15]

The net effect of a given mediator can vary depending on the state of activation of the target cell, the presence of other mediators near the target cell, and the ability of the target cell to release mediators that can augment or inhibit the primary mediator. As Fig. 128–2 illustrates, when there is a systemic spillover of excessive proinflammatory mediators, the patient presents with SIRS and possibly MODS. Shortly after this initial phase, counterregulatory pathways become activated, and there is a systemic spillover of excessive antiinflammatory mediators, representing a compensatory antiinflammatory response syndrome (CARS). The balance between pro- and antiinflammatory mechanisms determines the degree of inflammation, ranging from local antibacterial activity to systemic tissue toxicity or organ failure.[14]

CASCADE OF SEPSIS

3 The cascade leading to development of sepsis is complex and multifactorial, involving various mediators and cell lines.[14–16] Endothelial cells produce a variety of cytokines that mediate a primary mechanism of injury in sepsis. When injured, endothelial cells allow circulating cells such as granulocytes and plasma constituents to enter inflamed tissues, which can result in organ damage.

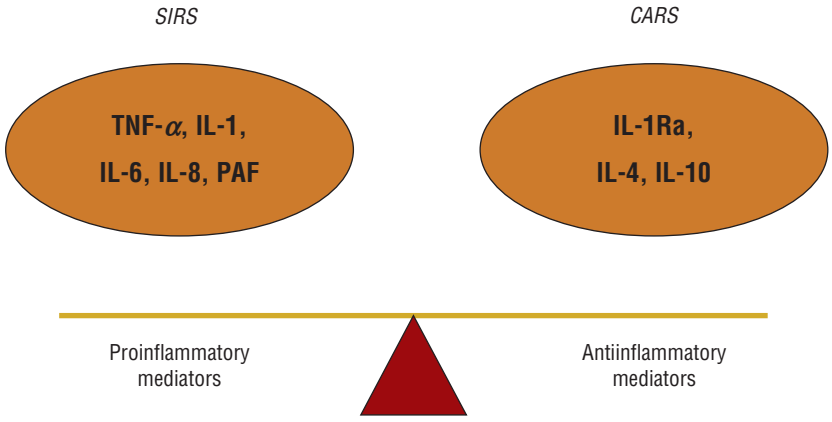

FIGURE 128-2. The balance between pro- and anti-inflammatory mediators. CARS, compensatory antiinflammatory response syndrome; IL, interleukin; IL-1RA, interleukin-1 receptor antagonist; SIRS, systemic inflammatory response syndrome; TNF, tumor necrosis factor.

The microcirculation is affected by sepsis-induced inflammation.[20] The arterioles become less responsive to either vasoconstrictors or vasodilators. The capillaries are less perfused, and there is neutrophil infiltration and protein leakage into the venules. Pulmonary dysfunction can result from the destructive mechanisms of neutrophils that are attracted to lung tissue through the action of mainly IL-8.

Activation of complement in sepsis leads to pathophysiologic consequences, including generation of anaphylactic toxins and other substances that augment or exaggerate the inflammatory response. Stimulation of leukocyte chemotaxis, phagocytosis with lysosomal enzyme release, increased aggregation and adhesion of platelets and neutrophils, and the production of toxic superoxide radicals are attributed, in part, to complement activation. Among these responses are the release of histamine from mast cells and the resultant increase in capillary permeability and the "third-spacing" of fluid in interstitial spaces.

The inflammatory process in sepsis is also directly linked to the coagulation system. Proinflammatory mechanisms that promote sepsis are also procoagulant and antifibrinolytic, whereas fibrinolytic mechanisms can be antiinflammatory.[21] A key endogenous substance involved in inflammation of sepsis is activated protein C, which enhances fibrinolysis and inhibits inflammation. Levels of protein C are reduced in patients with sepsis.[22]

COMPLICATIONS

The majority of patients with severe sepsis have dysfunction of two organs, and the three most frequent organ dysfunctions are respiratory, circulatory, and renal.[9] Shock is the most ominous complication associated with sepsis, and mortality occurs in approximately half of the patients with septic shock. Severe hypotension appears to be caused, in part, by the release of vasoactive peptides, such as bradykinin and serotonin, and by endothelial cell damage leading to the extravasation of fluids into interstitial spaces. Septic shock is associated with several complications, including disseminated intravascular coagulation, acute respiratory distress syndrome, and multiple organ failure.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is the inappropriate activation of the clotting cascade that causes formation of microthrombi, resulting in consumption of coagulation factors, organ dysfunction, and bleeding. Sepsis remains the most common cause of DIC. The incidence of DIC increases as the severity of sepsis increases. In sepsis alone, the incidence was 16% in comparison to 38% in septic shock.[23] DIC occurs in up to 50% of patients with gram-negative sepsis, but it is also common in patients with gram-positive sepsis.

DIC begins with the activation and production of the proinflammatory cytokines, such as TNF, IL-1, and IL-6, which appear to be the principal mediators, along with endotoxin, of endothelial injury, activation of the coagulation cascade, and inhibition of fibrinolysis. The combination of excessive fibrin formation, inhibited fibrin removal from a depressed fibrinolytic system, and endothelial injury results in microvascular thrombosis and DIC.[23]

Complications of DIC vary and depend on the target organ affected and the severity of the coagulopathy. DIC can produce acute renal failure, hemorrhagic necrosis of the GI mucosa, liver failure, acute pancreatitis, acute respiratory distress syndrome, and pulmonary failure. Furthermore, as the procoagulant state appears to be the key in the pathogenesis of MODS, coagulation dysfunction and MODS often coexist in sepsis.

ACUTE RESPIRATORY DISTRESS SYNDROME

Pulmonary dysfunction usually precedes dysfunction in other organs, and it can even initiate the development of SIRS with resultant MODS. Activated neutrophils and platelets adhere to the pulmonary capillary endothelium, initiating multiple inflammatory cascades with a release of a variety of toxic substances. There is diffuse pulmonary endothelial cell injury, increased capillary permeability, and alveolar epithelial cell injury.[24] Consequently, interstitial pulmonary edema occurs that gradually progresses to alveolar flooding and collapse. The end result is loss of functional alveolar volume, impaired pulmonary compliance, and profound hypoxemia.

Abnormalities of pathways of fibrin turnover after the pathogenesis of acute inflammation responses and fibrotic repair.[25] Coagulation is locally upregulated in the injured lung, whereas fibrinolytic activity is depressed. These abnormalities occur concurrently and favor alveolar fibrin deposition. Anticoagulant interventions that block the extrinsic coagulation pathway can protect against the development of pulmonary fibrin deposition as well as lung dysfunction and acute inflammation.[26] Overall, fibrin deposition in the injured lung and abnormalities of coagulation and fibrinolysis are integral to the pathogenesis of acute respiratory distress syndrome (ARDS).

HEMODYNAMIC EFFECTS

The hallmark of the hemodynamic effect of sepsis is the hyperdynamic state characterized by high cardiac output and an abnormally low systemic vascular resistance (SVR).[27] TNF-α and endotoxin directly depress cardiovascular function. Endotoxin depresses left ventricular function independent of changes in left ventricular volume or vascular resistance.

Persistent hypotension raises concern for the balance of oxygen delivery (DO_2) to the tissues and oxygen consumption (VO_2) by the tissues.[24,27] Sepsis results in a distributive shock characterized by inappropriately increased blood flow to particular tissues at the expense of other tissues, which is independent of specific tissue oxygen needs. This perfusion defect is accentuated by an increased precapillary atrioventricular shunt. If perfusion decreases, oxygen extraction increases, and the arteriovenous oxygen gradient widens. Cellular DO_2 is decreased, but VO_2 remains unaffected. When increased oxygen demand occurs without increased blood flow, the increased VO_2 is compensated by increased oxygen extraction. If perfusion decreases sufficiently in the face of high metabolic demands, then the reserve DO_2 can be exceeded, and tissue ischemia results. Significant tissue ischemia leads to organ dysfunction and failure. Therefore, systemic DO_2 relative to VO_2 should be optimized by increasing oxygen delivery or decreasing oxygen consumption in a hypermetabolic patient.

ACUTE RENAL FAILURE

Early acute kidney injury occurs in 42% to 64% of adult patients with sepsis and septic shock.[28,29] Without normal urine output, fluid overload in extravascular space including the lungs develops, leading to impairment of pulmonary gas exchange and severe hypoxemia. Consequently, compromised oxygen delivery exacerbates peripheral ischemia and organ damage. Adequate renal perfusion and a trial of loop diuretics should be initiated promptly in oliguric or anuric patients with MODS. In addition, renal replacement therapy such as continuous hemofiltration or intermittent hemodialysis should be used to facilitate volume and electrolytes.[30]

CLINICAL PRESENTATION

Table 128–2 lists some of the common clinical features of sepsis, although several of these findings are not limited to infectious processes. The initial clinical presentation can be referred to as signs and symptoms of early sepsis, defined as the first 6 hours. They are typically fever, chills, and change in mental status. Hypothermia can occur with a systemic infection, and this is often associated with a poor prognosis.[3,6] In patients with sepsis caused by gram-negative bacilli, hyperventilation can occur even before fever and chills, and it can lead to respiratory alkalosis as the earliest metabolic change.

Progression of uncontrolled sepsis leads to clinical evidence of organ system dysfunction as represented by the signs and symptoms attributed to late sepsis. With the exception of rapidly progressing cases as in meningococcemia, *P. aeruginosa,* or *Aeromonas* infection, the onset of shock is slow and usually follows a period of several hours of hemodynamic instability. Oliguria often follows hypotension. Increased glycolysis with impaired clearance of the resulting lactate by the liver and kidneys and tissue hypoxia because of hypoperfusion result in elevated lactate levels, contributing to metabolic acidosis. Altered glucose metabolism, including impaired gluconeogenesis and excessive insulin release, is evidenced by either hyperglycemia or hypoglycemia.

TABLE 128-2 Signs and Symptoms Associated with Sepsis

Early Sepsis	Late Sepsis
Fever or hypothermia	Lactic acidosis
Rigors, chills	Oliguria
Tachycardia	Leukopenia
Tachypnea	DIC
Nausea, vomiting	Myocardial depression
Hyperglycemia	Pulmonary edema
Myalgias	Hypotension (shock)
Lethargy, malaise	Hypoglycemia
Proteinuria	Azotemia
Hypoxia	Thrombocytopenia
Leukocytosis	ARDS
Hyperbilirubinemia	GI hemorrhage
	Coma

ARDS = acute respiratory distress syndrome; DIC = disseminated intravascular coagulation; GI = gastrointestinal.

PROGNOSIS

4 As the patient progresses from SIRS to sepsis to severe sepsis to septic shock, mortality increases in a stepwise fashion. Mortality rates are higher for patients with advanced age; preexisting disease, including chronic obstructive pulmonary disease, neoplasm, and human immunodeficiency virus (HIV) disease; ICU care; more failed organs; positive blood cultures; and *Pseudomonas* species infection.[5,9] In one analysis of cases, mortality increased with age from 10% in children to 38.4% in those 85 years or older.[1] ICU admission was required in 51.1% of patients with severe sepsis; of those patients, mortality was reported in 34.1%.[1] Mortality from severe sepsis and MODS is most closely related to the number of dysfunctioning organs. As the number of failing organs increased from two to five, mortality increased from 54% to 100% (Fig. 128–3).[24] Duration of organ dysfunction can also affect the overall mortality rate.

An elevated lactate concentration of >4 mmol/L in the presence of SIRS significantly increases ICU admission rates, and persistent

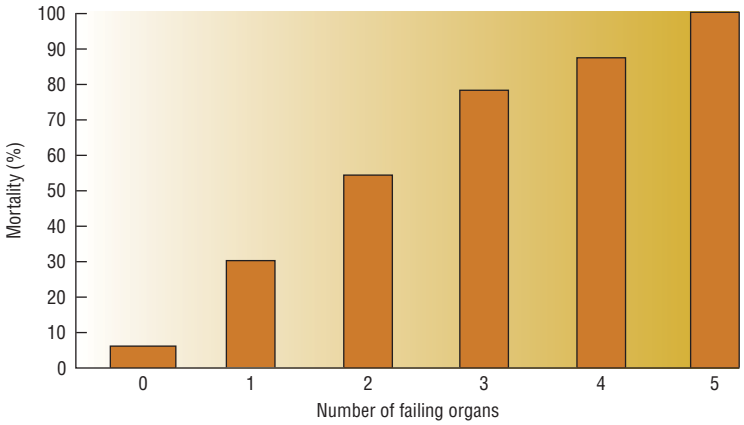

FIGURE 128-3. Mortality related to the number of failing organs.

elevations in lactate for more than 24 hours are associated with a mortality rate as high as 89%.[31] Inversely, patients with higher lactate clearance after 6 hours of emergency department intervention have improved outcome compared with those with lower lactate clearance. There was an ~11% decrease in the likelihood of mortality for each 10% increase in lactate clearance.[31]

TREATMENT

In 2008, a "surviving sepsis" campaign guideline for management of severe sepsis and septic shock was published as an international effort to increase awareness and improve outcome in severe sepsis.[32] The primary goals of therapy for patients with sepsis are (a) timely diagnosis and identification of the pathogen, (b) rapid elimination of the source of infection medically and/or surgically, (c) early initiation of aggressive antimicrobial therapy, (d) interruption of pathogenic sequence leading to septic shock, and (e) avoidance of organ failure. Supportive care such as stress ulcer prophylaxis and nutritional support is important to prevent complications during the stay in the ICU. Table 128–3 describes the summary of the surviving sepsis campaign treatment recommendations.

TABLE 128-3 Evidence-based Treatment Recommendations for Sepsis and Septic Shock

Recommendations	Recommendation Grades[a]
Initial resuscitation (first 6 hours)	
Early goal-directed goals, including CVP 8–12 mm Hg, MAP ≥65 mm Hg, central venous oxygen saturation ≥70%	1C
Antibiotic therapy	
IV broad-spectrum antibiotic within 1 hour of diagnosis of septic shock and severe sepsis against likely bacterial/fungal pathogens	1B
Reassess antibiotic therapy daily with microbiology and clinical data to narrow coverage	1C
Fluid therapy	
No clinical outcome difference between colloids and crystalloids	1B
Fluid challenges of 1000 mL of crystalloids or 300–500 mL of colloids over 30 minutes	1D
Vasopressors	
Norepinephrine and dopamine are the initial choices	1C
Maintain MAP ≥65 mm Hg	1C
Inotropic therapy	
Use dobutamine when cardiac output remains low despite fluid resuscitation and combined inotropic/vasopressor therapy	1C
Glucose control	
Use IV insulin to keep blood glucose ≤150 mg/dL	2C
Steroids	
IV hydrocortisone for septic shock when hypotension remains poorly responsive to adequate fluid resuscitation and vasopressors	2C
Hydrocortisone dose should be <300 mg/day	1A
Recombinant human activated protein C (drotrecogin)	
Consider in sepsis-induced organ dysfunction with high risk of death (typically APACHE II ≥25 or multiple organ failure) in the absence of contraindications	2B
Deep vein thrombosis prophylaxis	
Use either low-molecular-weight heparin or low-dose unfractionated heparin in preventing deep vein thrombosis	1A
Stress ulcer prophylaxis	
H2 receptor blocker or proton pump inhibitor is effective	1A, 1B

[a]Grades of Recommendation, Assessment, Development, and Evaluation (GRADE) system: a structured system for rating quality of evidence and grading strength of recommendation in clinical practice. Quality of evidence: high (grade A), moderate (grade B), low (grade C), or very low (grade D). Strength of recommendation: strong (grade 1) or weak (grade 2).

CVP = central venous pressure, MAP = mean arterial pressure.

Adapted from Dellinger RP, Levy MM, Carlet JM, et al. Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2008. Crit Care Med 2008;36: 296–327.

IDENTIFICATION OF THE PATHOGEN

The presence of clinical features suggesting sepsis should prompt further evaluation of the patient. In addition to obtaining a careful history of any underlying conditions and recent travel, injury, animal exposure, infection, or use of antibiotics, a complete physical examination should be performed to determine the source of the infection.

A collection of specimens should be sent for culture prior to initiating any antimicrobial therapy. Generally, at least two sets of blood samples from a peripheral vein and through a vascular access device should be obtained for aerobic and anaerobic culture. In critically ill septic patients, two or three sets of blood cultures should be collected without temporal separation between the sets.[33] With suspected catheter-related infection, a pair of blood cultures obtained through the catheter hub and a peripheral site should be obtained simultaneously.[33] In severe community-acquired pneumonia, blood cultures and respiratory secretions must be obtained. Urinary antigen detection of *Legionella* serogroup 1 is recommended during outbreaks. To document a soft tissue infection, a Gram stain and bacterial culture of any obvious wound exudates should be performed. A needle aspiration of a closed infection such as cellulitis or abscess may be needed for stain and bacterial culture. In abdominal infections, fluid collections identified by imaging studies should be aspirated for Gram stains and aerobic and anaerobic cultures.[33] A lumbar puncture is indicated in case of mental alteration, severe headache, or a seizure, assuming there are no focal cranial lesions identified by computed tomography scan. Further tests can be indicated to assess any systemic organ dysfunction caused by severe sepsis. The laboratory tests should include hemoglobin, white blood cell count with differential, platelet count, complete chemistry profile, coagulation parameters, serum lactate, procalcitonin, and arterial blood gases.

ELIMINATION OF THE SOURCE OF INFECTION

After the source of infection is identified, prompt efforts to eradicate that source should be initiated.[34] With an infected intravascular catheter, the catheter should be removed and cultured. Urinary tract catheters should be removed if association with sepsis is suspected. Suspicion of soft tissue (cellulitis or wound infection) or bone involvement should lead to aggressive debridement of the affected area. Evidence of an abscess or sepsis associated with any intraabdominal pathology should prompt surgical intervention.

ANTIMICROBIAL THERAPY

5 The most recent guidelines from the Surviving Sepsis Campaign recommended starting IV antibiotic therapy as early as possible because early administration of broad-spectrum antibiotics is critical in decreasing the risk of mortality.[32] In a large cohort of ICU patients with severe sepsis, early administration (within 1 hour vs 6 hours of diagnosis) of broad-spectrum antibiotics was independently associated with lower hospital mortality.[35]

In a study evaluating 904 patients with microbiologically confirmed severe sepsis or septic shock, appropriate initial antimicrobial therapy was an important determinant of survival.[7] The 28-day mortality was 24% in patients who received appropriate initial antimicrobial treatment versus 39% in those who received inappropriate initial treatment. Furthermore, in patients who had septic shock, delays in the initiation of effective antimicrobial therapy after the onset of hypotension were significant predictors of mortality.[36,37] Therefore, early administration of appropriate antimicrobial therapy is critical in the treatment of severe sepsis.

Selection of Antimicrobial Agents

The selection of an empiric regimen should be based on the suspected site of infection, the most likely pathogens, acquisition of the organism from the community or hospital, the patient's immune status, and the antibiotic susceptibility and resistance profile for the institution. All patients should be treated initially with parenteral antibiotics for optimal drug concentrations within the first hour of recognition of severe sepsis after appropriate cultures have been taken.[32] Empiric therapy for an immunocompromised patient should be broad enough to cover likely pathogens and penetrate adequately into the presumed infection site. Once the pathogen and its susceptibility pattern are known, the antimicrobial regimen should be modified accordingly.

Table 128–4 lists antimicrobial regimens that can be used empirically based on the possible source of infection. In the nonneutropenic patient with a urinary tract infection, ceftriaxone and fluoroquinolones are generally recommended. When there is increased risk of *P. aeruginosa* in sepsis or hospital-acquired infections, an antipseudomonal antibiotic, such as ceftazidime, is recommended.[38]

S. pneumoniae is the most common cause of community-acquired pneumonia, and it accounts for ~60% of all deaths. The rising incidence of penicillin-resistant *S. pneumoniae* requires empiric use of newer "respiratory" fluoroquinolones. Newer fluoroquinolones, such as levofloxacin and moxifloxacin, can be used as monotherapy, as they offer excellent coverage against penicillin-resistant pneumococci and aerobic gram-negative bacteria, as well as atypical pathogens, including *Legionella pneumophila, Mycoplasma pneumoniae,* and *Chlamydia pneumoniae.*[39] Clarithromycin and azithromycin are effective against atypical pathogens and better tolerated than erythromycin.

In nosocomial pneumonia, enteric gram-negative bacteria such as *Enterobacter* and *Klebsiella* species and *P. aeruginosa* are the major pathogens, in addition to *S. aureus.* If *P. aeruginosa* infection is suspected, ß-lactam antipseudomonal agents (ceftazidime or cefepime), antipseudomonal fluoroquinolone (ciprofloxacin or levofloxacin), or an aminoglycoside should be included in the regimen[40] When *S. aureus* is likely to be methicillin-resistant, linezolid may be preferred to vancomycin because of the poor penetration of vancomycin into the lungs, as well as the worldwide emergence of glycopeptide intermediately resistant *S. aureus.*[41,42]

Secondary peritonitis as a consequence of perforation of the GI tract is usually polymicrobial involving enteric aerobes and anaerobes, and as many as five organisms are isolated per patient. In general, if resistance for a given antibiotic is greater than 10% to 20% for a common intraabdominal pathogen in the community, that agent should be avoided. Because of widespread resistance of *Escherichia coli* to ampicillin/sulbactam, it is no longer recommended.[43] Emerging fluoroquinolone-resistant *E. coli,* as well as areas of high prevalence of extended-spectrum β-lactamase-producing strains of *Klebsiella* species and *E coli,* should be considered in choosing empiric therapy.[43] *Bacteroides fragilis,* the major pathogen, has shown uniform susceptibility to metronidazole, carbapenems, and β-lactam/β-lactamase inhibitors.[44] Although moxifloxacin demonstrates activity against *B. fragilis,* it should be avoided in patients who recently received quinolone therapy.

In addition to surgical intervention, broad-spectrum antibiotics, such as β-lactamase inhibitor combination agent (piperacillin/tazobactam), are appropriate in treating intraabdominal infections.[45] Carbapenems such as imipenem, meropenem, and doripenem are indicated in the treatment of resistant pathogens, including Enterobacteriaceae and *P. aeruginosa,* in critically ill patients.[45,46]

Skin and soft tissue infections (SSTIs) range from cellulitis to rapidly progressive necrotizing fasciitis, which may be associated with septic shock and toxic shock syndrome. Staphylococci and streptococci long have been the leading causes of SSTIs, but severe SSTIs can be caused also by indigenous aerobes and anaerobes such as *Clostridium* species.[47] Early initiation of appropriate empiric broad-spectrum antimicrobial therapy is essential and should include coverage against methicillin-resistant *S. aureus* (MRSA) due to the high prevalence of community-associated MRSA strains.[47,48] Vancomycin, daptomycin, and linezolid have comparable clinical efficacy and safety data for complicated skin and skin-structure infections caused by MRSA.[49,50]

The antimicrobial regimen should be reassessed after 48 to 72 hours based on the microbiological and clinical data. Once the culture results and antimicrobial susceptibility data return, therapy should be directed toward the isolated pathogen as part of good antibiotic stewardship to prevent drug toxicities and the development of nosocomial superinfections with *Candida* species, *Clostridium difficile,* or vancomycin-resistant enterococcus.[51] Furthermore, improved patient care outcomes have been demonstrated with such deescalation of antibiotic therapy.[52]

Pathophysiologic changes have been reported in sepsis that can affect drug distribution, and adjusted dosing regimens are required

TABLE 128-4 Empiric Antimicrobial Regimens in Sepsis

Infection (Site or Type)	Antimicrobial Regimen: Community-acquired	Antimicrobial Regimen: Hospital-acquired	
Urinary tract	ceftriaxone or ciprofloxacin/levofloxacin	ciprofloxacin/levofloxacin or ceftriaxone or ceftazidime	
Respiratory tract	levofloxacin[a]/moxifloxacin or ceftriaxone + clarithromycin/azithromycin	piperacillin/tazobactam or ceftazidime or cefipime + levofloxacin/ciprofloxacin or aminoglycoside	
Intraabdominal	piperacillin/tazobactam or ciprofloxacin + metronidazole	piperacillin/tazobactam or carbapenem[b]	
Skin/soft tissue	vancomycin or linezolid or daptomycin	vancomycin + ampicillin/sulbactam or piperacillin/tazobactam	
Catheter-related		vancomycin	
Unknown		piperacillin/tazobactam or ceftazidime/cefipime or imipenem/meropenem	+/- vancomycin not gentamicin.

[a]750 mg orally once daily.
[b]Imipenem, meropenem, doripenem.

in critically ill patients with sepsis.[53] Initially high creatinine clearance can be seen in patients with normal serum creatinine because of increased renal preload. Volume of distribution can increase because of fluid accumulation from leaky capillaries and/or altered protein binding. Consequently, some antimicrobial agents, including aminoglycosides, β-lactams, carbapenems, and vancomycin, can result in lower peak serum concentrations with usual doses. However, as sepsis progresses, organ perfusion decreases because of significant myocardial depression and leads to multiple organ dysfunction. Consequently, clearance of antimicrobial agents is decreased, prolonging the elimination half-life and accumulation of metabolites. Hence, in addition to selecting the most appropriate antimicrobial agents, a clinician must ensure effective antibiotic usage, such as proper dosing, interval of administration, optimal duration of treatment, monitoring of drug levels when appropriate, and avoidance of unwanted drug interactions. The lack of adherence to these requirements can lead to suboptimal or excessive tissue concentrations that can promote antibiotic resistance, toxicity, and inadequate efficacy despite appropriate antibiotic selection.

Monotherapy with a broad-spectrum β-lactam antibiotic is as efficacious as and less toxic than a combination of β-lactam and an aminoglycoside as empirical therapy for critically ill patients with severe sepsis or septic shock.[54,55] There is no evidence that combination therapy is more effective than monotherapy. However, some experts prefer combination therapy for patients with *Pseudomonas* infections and for neutropenic patients with severe sepsis or septic shock.[32,56]

CLINICAL CONTROVERSIES

The rationale of antibiotic combination therapy for severe infections includes broadening the antibacterial spectrum, exertion of additive or synergistic effects, and possible reduction of emergence of resistant bacteria or superinfection. Combinations such as a β-lactam and an aminoglycoside have been evaluated[54,55] However, superiority of the combination therapy over single-agent therapy was not demonstrated with the exception of those patients with rapidly declining diseases such severe sepsis. With the introduction of highly bactericidal, broad-spectrum antibiotics such as piperacillin/tazobactam, ceftazidime, cefipime and the carbapenems, more studies have compared the efficacy and toxicities of monotherapy against a β-lactam and an aminoglycoside combination regimen during the last two decades.

Monotherapy with a broad-spectrum β-lactam antibiotic is as efficacious and less toxic than a combination of β-lactam and an aminoglycoside as empirical therapy for critically ill patients with severe sepsis or septic shock.[32,54] However, it would be premature to initiate monotherapy for all patients with severe sepsis as standard of care due to limitations in the clinical trials such as small sample sizes (less than 200 patients) and the variability in antimicrobials used.[55,56]

Antifungal Therapy

Candida species are most frequently associated with fungal infections, and the resulting candidemia is frequently associated with sepsis syndrome and a high mortality rate.[13,57] Septic shock caused by *C. albicans* demonstrated 24.6% survival with initial appropriate therapy but only 4.6% survival without (ninefold decrease).[11] Empirical fluconazole therapy for suspected nosocomial bloodstream infections can be appropriate for hospitalized patients at high risk for fungal infections, including those receiving total parenteral nutrition, with bowel perforation, or with persistent or new signs and symptoms of infections despite receiving broad-spectrum antibacterial therapy. Of the patients with candidemia, mortality rates were lowest for those who began empirical fluconazole therapy on day 0 (15%) and highest for those who began on day 3 or later (41%).[58] Although prompt empirical fluconazole therapy significantly affects mortality rates of hospitalized patients with candidemia, it can increase overprescribing of antifungal agents for patients without candidemia. Rapid diagnostic tests or identification of unique risk factors for bloodstream infections caused by *Candida* species are needed.

Treatment of invasive candidiasis involves amphotericin B–based preparations, azole antifungal agents, and echinocandin antifungal agents, or combinations. The choice depends on the clinical status of the patient, the fungal species and its susceptibility, the relative drug toxicity, the presence of organ dysfunction that would affect drug clearance, and the patient's prior exposure to antifungal agents.

Fluconazole is less toxic and easier to administer than amphotericin B. However, fluconazole resistance in *C. albicans* has been well described among HIV-infected individuals and is increasing in immunocompetent adults.[59] *C. glabrata* often has reduced susceptibility to fluconazole. Itraconazole exhibits a similar activity profile as fluconazole and is well known to be active against mucosal forms of candidiasis. However, the parenteral form of itraconazole is no longer available. Voriconazole appears to be active against *Candida* species, including fluconazole-resistant isolates. A worldwide study will aid in analyzing voriconazole for the indication of treatment of serious invasive, fluconazole-resistant *Candida* infections, including *C. krusei*.[59,60]

Caspofungin, the first echinocandin antifungal agent, appears to be potent against all *Candida* species, including *C. glabrata, C. krusei,* and *Candida lusitaniae,* as well as *Aspergillus* species. IV caspofungin was equally effective but better tolerated than amphotericin B deoxycholate for invasive candidiasis.[61] In an international, randomized, double-blind trial, the micafungin 100 mg group was noninferior to caspofungin for the treatment of candidemia and other forms of invasive candidiasis demonstrated (76.4% vs 72.3%).[62] Anidulafungin, the latest echinocandin to be approved, achieved a success rate of 73.2% against invasive candidiasis in comparison to the 61.1% treatment success rate of fluconazole.[63] The difference was not statistically significant.

In general, suspected systemic mycotic infection leading to sepsis in nonneutropenic patients should be treated empirically with parenteral fluconazole, caspofungin, anidulafungin, or micafungin.[59] An echinocandin is preferred for a patient with recent azole exposure or if the patient is clinically unstable because of its greater activity against fluconazole-resistant *Candida* species and non-*Albicans* species, including *C. glabrata* and *C. krusei*.[59,64] In neutropenic patients, a lipid formulation of amphotericin, caspofungin, or voriconazole is recommended. Azoles should be avoided for empiric therapy in patients who have received an azole for prophylaxis.[59]

Duration of Therapy

The average duration of antimicrobial therapy in the normal host with sepsis is 7 to 10 days, and fungal infections can require 10 to 14 days.[7,32,40,59] However, the duration can be longer in patients with a slow clinical response, undrainable focus of infection, or neutropenia. After the patient is hemodynamically stable, has been afebrile for 48 to 72 hours, has a normalizing white blood cell (WBC) count, and is able to take oral medications, then a "step-down" from parenteral to oral antibiotics can be considered for the remaining duration of therapy. Treatment can continue considerably longer if the infection is persistent. In a neutropenic patient, therapy is usually continued until the patient is no longer neutropenic and has been afebrile for at least 72 hours.

Procalcitonin may also be used to guide the length of antibiotic therapy. Procalcitonin is a biomarker that increases in response to endotoxins and inflammatory cytokines released during systemic bacterial infections.[65,66] A reduction in antibiotic exposure has been reported in patients with lower respiratory tract infections using procalcitonin levels as a guide for discontinuing antibiotics. Results from a limited number of studies using procalcitonin as a marker to discontinue antibiotics in patients with severe sepsis or septic shock and surgical intensive care patients are promising, and more trials are expected in the near future.[65,66]

HEMODYNAMIC SUPPORT

A high cardiac output and a low systemic vascular resistance characterize septic shock. Patients can have hypotension as a result of low systemic vascular resistance and abnormal distribution of blood flow in the microcirculation, resulting in compromised tissue perfusion. Because approximately half of patients with septic shock die of multiple organ system failure, they should be monitored carefully, and aggressive hemodynamic support should be initiated.

Hemodynamics change rapidly in sepsis, and noninvasive evaluation can give inaccurate assessment of filling pressures and cardiac output, requiring a right-sided heart catheter in the ICU setting.[67] Hemodynamic support can be divided into three main categories: fluid therapy, vasopressor therapy, and inotropic therapy.

Fluid Therapy

6 Septic patients have enormous fluid requirements as a result of peripheral vasodilation and capillary leakage.[67] In ~50% of septic patients who initially present with hypotension, fluids alone will reverse hypotension and restore hemodynamic stability. Rapid fluid resuscitation improves the 28-day survival rate in patients with sepsis-induced hypoperfusion.[32] The goal of fluid therapy is to maximize cardiac output by increasing the left ventricular preload, which will ultimately restore tissue perfusion.[67] Fluid administration should be titrated to clinical end points such as heart rate, urine output, blood pressure, and mental status. Increased serum lactate, a by-product of cellular anaerobic metabolism, should normalize as tissue perfusion improves.

Isotonic crystalloids, such as 0.9% sodium chloride (normal saline), and lactated Ringer solution are commonly used for fluid resuscitation. A patient in septic shock typically requires up to 10 L of crystalloid solution during the first 24-hour period. These solutions distribute into the extracellular compartment. Approximately 25% of the infused volume of crystalloid remains in the intravascular space, whereas the balance distributes to extravascular spaces. Although this could impair diffusion of oxygen to tissues, clinical impact is unproven.

The most commonly used colloids are 5% albumin, a naturally occurring plasma protein, and 6% hetastarch, a synthetic colloid formulation. These solutions offer more rapid restoration of intravascular volume because they produce greater intravascular volume expansion per quantity of volume infused. Colloids produce less peripheral edema than crystalloid, but there is no significant clinical impact. The use of colloid solutions and blood products can be particularly important if there is significant blood loss associated with sepsis or if the patient had severe preexisting anemia.

Meta-analysis of clinical studies comparing crystalloid and colloid resuscitation indicated no clinical outcome differences.[68] The Saline versus Albumin Fluid Evaluation (SAFE) trial found no difference in the 28-day mortality rate in critically ill patients (21.1% with saline vs 20.9% with albumin).[69] Although crystalloid solutions require two to four times more volume than colloids, they are generally recommended for fluid resuscitation because of the lower cost. However, colloids can be preferred, especially when the serum albumin is less than 2.0 g/dL.

Central venous pressure (CVP) is used to monitor fluid status in patients with septic shock. Initial fluid resuscitation should target a CVP between 8 and 12 mm Hg within the first 6 hours of presentation.[32] Fluid challenges should continue until hemodynamic stability is reached as long as CVP is at goal. The rate of fluid administration should be reduced if hemodynamic measures do not improve despite adequate or increasing cardiac filling pressures. Resuscitation typically includes IV normal saline 500 mL every 15 minutes until the target CVP is reached.

Patients receiving fluid challenges require close monitoring of volume status to avoid pulmonary and systemic edema. Aggressive volume expansion can cause an increase in pulmonary capillary pressure, leading to an increase in lung water and associated hypoxemia.[70] There is no significant difference in the incidence of pulmonary edema between the crystalloid and colloid solutions.

Vasopressor and Inotropic Therapy

When fluid resuscitation alone provides inadequate arterial pressure and organ perfusion, vasopressors and inotropic agents should be initiated. Inotropic agents such as dopamine and dobutamine have been effective in improving cardiac output by increasing cardiac contractility. Vasopressors such as norepinephrine should be considered when a systolic blood pressure is less than 90 mm Hg or mean arterial pressure (MAP) is <65 mm Hg after adequate left ventricular preload and inotrope therapy. Although inotropes and vasopressors are effective in life-threatening hypotension and in improving cardiac index, there are significant complications such as tachycardia and myocardial ischemia and infarction as a result of the change in myocardial oxygen consumption in patients with coexisting coronary disease. Thus, a catecholamine infusion should be titrated gradually to restore MAP without impairing stroke volume.

7 Agents commonly considered for vasopressor or inotropic support include dopamine, dobutamine, norepinephrine, phenylephrine, and epinephrine (Table 128–5).[71] Norepinephrine should generally be considered to be the first-choice vasopressor in septic shock after failure to restore adequate blood pressure and organ perfusion with appropriate fluid resuscitation. Norepinephrine is a potent α-adrenergic agent with less pronounced β-adrenergic activity. It increases MAP and systemic vascular resistance because of its vasoconstrictive effects on peripheral

TABLE 128-5 Receptor Activity of Cardiovascular Agents Commonly used in Septic Shock

Agent	α_1	α_2	β_1	β_2	Dopaminergic
Dopamine	++/+++	?	++++	++	++++
Dobutamine	+	+	++++	++	0
Norepinephrine	+++	+++	+++	+/++	0
Phenylephrine	++/+++	+	?	0	0
Epinephrine	++++	++++	++++	+++	0

α_1 = α_1-adrenergic receptor, α_2 = α_2-adrenergic receptor, β_1 = β_1-adrenergic receptor, β_2 = β_2-adrenergic receptor, 0 = no activity, ++++ = maximal activity, ? = unknown activity.

vascular beds. Doses of 0.01 to 3 mcg/kg/min can reliably increase blood pressure with little changes in heart rate or cardiac index (CI). Despite the earlier concern of decreased renal blood flow associated with norepinephrine, data in humans and animals demonstrate a norepinephrine-induced renal blood flow as well as urine and cardiac output.[71] Norepinephrine is a more potent agent than dopamine in refractory septic shock. Norepinephrine resulted in greater increases in arterial blood pressure in comparison to patients with septic shock who were treated with dopamine (93% with norepinephrine vs 31% with dopamine).[72] Norepinephrine was also associated with a higher rate of survival compared with dopamine and epinephrine.[73]

Dopamine is a natural precursor of norepinephrine and epinephrine, and it exhibits dose-dependent pharmacologic effects. It is an α- and β-adrenergic agent with dopaminergic activity. Doses of >5 mcg/kg/min increase MAP and cardiac output, primarily because of the increase in heart rate and cardiac contractility through stimulation of β-adrenergic receptors. At higher doses, α-adrenergic effects predominate, resulting in arterial vasoconstriction. Because of combined vasopressor and inotropic effects, dopamine is more useful in patients with hypotension and compromised systolic function. However, it is also more arrhythmogenic and can cause more tachycardia.[32,73,74] It should be used with caution in patients who have underlying heart disease.

Phenylephrine, a selective α_1-agonist, has rapid onset, short duration, and primary vascular effects, and it is least likely to produce tachycardia. Limited data suggest it can increase blood pressure modestly in fluid-resuscitated patients, and it does not appear to impair cardiac or renal function. Phenylephrine appears useful when tachycardia limits the usage of other vasopressors.[67,71]

Epinephrine is a nonspecific α- and β-adrenergic agonist. Ranging from 0.1 to 0.5 mcg/kg/min, cardiac output is increased at lower doses, and vasoconstriction occurs predominantly at higher doses. Epinephrine should be reserved for patients who fail to respond to traditional therapies for increasing or maintaining blood pressure, as it impairs blood flow to the splanchnic system, increases the lactate level, and causes dysrhythmia more frequently than other vasoactive agents.[67,73]

During hypotension, endogenous vasopressin levels increase and maintain arterial blood pressure, as vasopressin is a direct vasoconstrictor without inotropic or chronotropic effects. However, there is a vasopressin deficiency in septic shock most likely caused by inadequate production. Low doses of vasopressin (0.01–0.04 units/min) produce a significant increase in MAP in septic shock, and it may be beneficial to add vasopressin in severe sepsis and septic shock that is refractory to other vasopressors.[71] Vasopressin should not be used as a single agent for refractory hypotension. Although it can be used to reduce norepinephrine requirements, this has not been shown to improve mortality rates.[75]

Dobutamine is a β-adrenergic inotropic agent that many clinicians consider to be the preferred drug for improvement of cardiac output and oxygen delivery, particularly in early sepsis before significant peripheral vasodilation has occurred. Doses of 2 to 20 mcg/kg/min increases the CI, ranging from 20% to 66%. However, heart rate often increases significantly.[67] Dobutamine should be considered in severely septic patients with low CI but adequate filling pressures and blood pressure. A vasopressor such as norepinephrine and an inotrope such as dobutamine can be used to maintain both MAP and cardiac output.

In summary, for the septic patient with clinical signs of shock and significant hypotension unresponsive to aggressive fluid therapy, norepinephrine is the preferred agent for increasing MAP. Epinephrine should be considered for refractory hypotension. Dopamine and epinephrine are more likely to induce or exacerbate tachycardia than norepinephrine and phenylephrine. In a septic patient with low CI after adequate fluid therapy and adequate MAP, dobutamine is the first-line agent. Alternatively, dopamine in moderate doses (5–10 mcg/kg/min) can also be used as an initial agent because of its selective effect on increasing cardiac output with its minimal effect on systemic vascular resistance.

EARLY GOAL-DIRECTED THERAPY

8 Initial resuscitation of a patient in severe sepsis or sepsis-induced tissue hypoperfusion should begin as soon as the syndrome is recognized. A randomized, controlled trial evaluated the timing of the goal-directed therapy involving adjustments of cardiac preload, afterload, and contractility to balance oxygen delivery with demand prior to admission to the ICU.[76] The goals during the first 6 hours included CVP of 8 to 12 mm Hg, MAP ≥65 mm Hg, urine output ≥0.5 mL/kg/h, and a central venous or mixed venous oxygen saturation ≥70%. During the first 6 hours of resuscitation, the early goal-directed therapy group had a central venous catheter placed and received more fluid than with traditional therapy (5 vs 3.5 L), dobutamine therapy to a maximum of 20 mcg/kg/min, and red blood cell transfusions. The 28-day mortality rate was 30% in the early goal-directed therapy group, in comparison to 46.5% in the traditional therapy group consisting of fluid resuscitation, followed by vasopressor therapy if required. Increased oxygen delivery from the red blood cell transfusions to achieve a hematocrit of ≥30% in the early goal-directed therapy group appeared to be the primary difference between the two groups. One institution evaluated the impact of 6-hour sepsis care bundle and found the compliance rate to be 52%.[77] The noncompliant group had a more than twofold increase in hospital mortality in comparison to the compliant group (49% vs 23%).

ADJUNCTIVE THERAPIES

ARDS and hypoxia are common in septic patients, even in those without pulmonary infection. Oxygen therapy is indicated to maintain oxygen saturation greater than 90%, and with progressive pulmonary insufficiency, the patient can require assisted ventilation.

9 Hyperglycemia is frequently associated with sepsis regardless of the presence of diabetes prior to sepsis, and it is usually quite refractory to exogenous insulin. Intensive insulin therapy is no longer the standard of care in critically ill patients. Results from a parallel, randomized control trial showed that more patients receiving intensive insulin therapy (target serum glucose of 81–108 mg/dL) at 90 days died compared with patients receiving conventional insulin therapy (target ≤180 mg/dL).[78,79] Hypoglycemia is the most common adverse effect of intensive insulin therapy. Even though there was no difference in mortality in the subgroup of patients with severe sepsis, a glucose range of 140 to 180 mg/dL or less than 150 mg/dL is recommended for the majority of critically ill patients to improve the outcome while reducing the risk of hypoglycemia.[32,80]

10 The role of corticosteroids has been the subject of much controversy in the management of septic patients.[81,82] Inflammatory cytokines contribute to adrenal insufficiency during sepsis. Corticosteroids have been advocated as adjunctive therapy in patients with severe sepsis and septic shock, as they prevent the release of proinflammatory cytokines.

A multicenter, randomized, controlled trial demonstrated significant shock reversal and decrease in mortality (absolute reduction 10%) in patients with severe septic shock who were given low-dose corticosteroids.[83] Fludrocortisone 50 mcg orally and hydrocortisone 200 to 300 mg/day for 7 days in three or four divided doses or by continuous infusion were used in patients with adrenal

insufficiency, requiring high-dose or increasing vasopressor therapy within the first 8 hours of septic shock.[83] There was no benefit for those patients without adrenal insufficiency. An adrenocorticotropic hormone (ACTH) stimulation test has been used to identify those patients who have a relative adrenal insufficiency who should then receive supplemental steroid. However, in the large multicenter trial, the Corticosteroid Therapy of Septic Shock (CORTICUS), the patients benefited regardless of ACTH stimulation test outcome.[82]

The Surviving Sepsis Campaign recommends IV hydrocortisone for adult patients with septic shock whose blood pressure is unresponsive to fluids and vasopressors.[32,84] Corticosteroids should be weaned once a patient is off vasopressors, although comparative clinical trials comparing whether steroids should be abruptly discontinued or tapered are lacking.

CLINICAL CONTROVERY

A systematic review reported a significant reduction in 28-day all cause mortality and hospital mortality in patients receiving prolonged courses (>5 days) of low-dose corticosteroid therapy (≤300 mg hydrocortisone or equivalent/day).[81] The Corticosteroid Therapy of Septic Shock (CORTICUS) trial found no survival benefit among patients who received prolonged courses of hydrocortisone, but reported a trend in shock reversal for patients who received hydrocortisone.[82] Based on the current Surviving Sepsis guidelines, corticosteroids should be reserved for patients who continue to be hypotensive despite adequate fluids and vasopressor therapy, are maintained on an outpatient corticosteroid regimen, or may be initiated at physician discretion.

Deep vein thrombosis prophylaxis with either low-dose unfractionated heparin or low-molecular-weight heparin should be initiated in general ICU patients, including those with severe sepsis and septic shock.[32] Similarly, stress ulcer prophylaxis should be initiated in all patients with severe sepsis and septic shock.[32] Proton pump inhibitors and H_2 receptor antagonists are equivalent in their ability to increase gastric pH.

IMMUNOTHERAPY

Despite the initial enthusiasm for immunotherapeutic interventions for sepsis, overall results have been generally disappointing, with the exception of drotrecogin alfa (recombinant human activated protein C, rhAPC), an endogenous anticoagulant with antiinflammatory properties. During severe sepsis, the activation of protein C is inhibited by inflammatory cytokines.

11 Drotrecogin, the first antiinflammatory agent to be approved for sepsis, promotes fibrinolysis and the inhibition of coagulation and inflammation. The Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) trial studied the effects of 96 hours of continuous infusion (24 mcg/kg/h) of rhAPC.[22] All-cause mortality at 28 days was significantly reduced from 30.8% with placebo to 24.7% in those receiving drotrecogin. However, a major risk associated with drotrecogin is hemorrhage. Serious bleeding, including intracranial hemorrhage and a life-threatening bleeding episode, occurred in 3.5% of patients who received drotrecogin in comparison to 2% of patients in the placebo group. Regardless, drotrecogin appears to have a significant role in the treatment of septic shock. Currently, drotrecogin is recommended in patients at high risk of death, including Acute Physiology and Chronic Health Evaluation (APACHE) II score ≥25, sepsis-induced multiple organ failure, septic shock, and sepsis-induced ARDS and with no absolute contraindication related to bleeding risk.[85] Cost–benefit analysis studies support the use of drotrecogin for patients at high risk of death, especially for those with APACHE II scores greater than 25.[22,86]

Subanalysis of the PROWESS trial demonstrated significant absolute risk reductions in 28-day and in-hospital mortality among patients 75 years or older (15.5% and 15.6%, respectively) in comparison to the placebo group.[87,88] There was no significant difference between the drotrecogin-treated group and the placebo group with respect to the incidences of serious bleeding (3.9% vs 2.2%). A randomized, placebo-controlled multicenter trial evaluating the efficacy of drotrecogin for adults who had severe sepsis and a low risk of death defined by an APACHE score <25 or single organ failure showed no significant difference between the placebo and the treatment groups in terms of the 28-day mortality rate (17% vs 18.5%, respectively).[89] The incidence of serious bleeding was higher in the treatment group than in the placebo group (3.9% vs 2.2%). Consequently, drotrecogin should not be used in patients with severe sepsis and low risk of death.

CONCLUSION

The diagnosis and management of severe sepsis and septic shock are challenging. The updated Surviving Sepsis Campaign international guidelines for management of severe sepsis and septic shock incorporate newer evidence-based interventions with the purpose of improving morbidity and mortality. Many institutions are following sepsis protocols, including initiation of early appropriate empiric antibiotics, restoration of tissue perfusion, initiation of vasopressor support, and other supportive measures to improve overall patient outcomes. The use of standardized treatment protocols in addition to newer treatment modalities in patients with severe sepsis and septic shock can continue to have an impact on the overall morbidity and mortality rate.

CARS: Compensatory antiinflammatory response syndrome
CI: Cardiac index
CORTICUS: Corticosteroid Therapy of Septic Shock (trial)
CVP: Cardiac venous pressure
DIC: Disseminated intravascular coagulation
DO_2: Oxygen delivery to tissues
HIV: Human immunodeficiency virus
ICU: Intensive care unit
IL: Interleukin
IL-1RA: Interleukin-1 receptor antagonist
MAP: Mean arterial pressure
MODS: Multiple-organ dysfunction syndrome
MRSA: Methicillin-resistant *Staphylococcus aureus*
PAF: Platelet-activating factor
PROWESS: Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (trial)
rhAPC: Recombinant human activated protein C
SAFE: Saline versus Albumin Fluid Evaluation (trial)
SIRS: Systemic inflammatory response syndrome

SSTIs: Skin and soft tissue infections
SVR: Systemic vascular resistance
TNF: Tumor necrosis factor
VO_2: Oxygen consumption
WBC: White blood cell

CHAPTER 129

Superficial Fungal Infections

THOMAS E. R. BROWN, LINDA D. DRESSER AND THOMAS W. F. CHIN

KEY CONCEPTS

1. Vulvovaginal candidiasis (VVC) can be classified as uncomplicated or complicated. This classification is useful in determining appropriate pharmacotherapy.
2. *Candida albicans* is the major pathogen responsible for VVC. The number of cases of non–*C. albicans* species appears to be increasing.
3. Signs and symptoms of VVC are not pathognomonic, and reliable diagnosis must be made with laboratory tests.
4. *C. albicans* is the predominant species causing all forms of mucosal candidiasis. Important host and exogenous risk factors have been identified that predispose an individual to the development of mucosal candidiasis. In oropharyngeal and esophageal candidiasis, the key risk factor is impaired host immune system.
5. A topical agent is the first choice for treating oropharyngeal candidiasis. Systemic therapy can be used in patients who are not responding to an adequate trial of topical treatment or are unable to tolerate topical agents and in those at high risk for systemic candidiasis. Fluconazole and itraconazole solution are the most effective azole agents.
6. In esophageal candidiasis, topical agents are not of proven benefit; fluconazole or itraconazole solution is the first choice.
7. Patients with human immunodeficiency virus (HIV) infection must be on concurrent optimal antiretroviral therapy, which is important for the prevention of recurrent and refractory candidiasis.
8. Primary or secondary prophylaxis of fungal infection is not recommended routinely for HIV-infected patients; use of secondary prophylaxis should be individualized for each patient.
9. Topical agents are first-line treatment for fungal skin infections. Oral therapy is preferred for the treatment of extensive or severe infection or those of tinea capitis or onychomycosis.
10. Oral agents, in particular terbinafine and itraconazole, are first-line treatment for toenail and fingernail onychomycosis.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Superficial mycoses are among the most common infections in the world and the second most common vaginal infections in North America. Mucocutaneous candidiasis can occur in three forms—oropharyngeal, esophageal, and vulvovaginal disease—with oropharyngeal and vulvovaginal disease being the most common. These infections were reported in humans as far back as 1839. Over the past 15 to 20 years, the occurrence rates of some fungal infections have increased dramatically. The prevalence of fungal skin infections varies throughout different parts of the world, from the most common causes of skin infections in the tropics to relatively rare disorders in the United States. This chapter reviews the pharmacotherapy of vulvovaginal candidiasis, oropharyngeal and esophageal candidiasis, and common dermatophyte infections.

VULVOVAGINAL CANDIDIASIS

1 *Vulvovaginal candidiasis* (VVC) refers to infections in individuals with or without symptoms who have positive vaginal cultures for *Candida* species. Depending on episodic frequency, VVC can be classified as either sporadic or recurrent.[1] This classification is essential to understanding the pathophysiology, as well as the pharmacotherapy, of VVC. Furthermore, VVC may be defined as uncomplicated, which refers to sporadic infections that are susceptible to all forms of antifungal therapy regardless of the duration of treatment, or complicated, in which consideration of factors affecting the host, microorganism, and pharmacotherapy all have an essential role in successful treatment.[1] Complicated VVC includes recurrent VVC, severe disease, non–*Candida albicans* candidiasis, and host factors, including diabetes mellitus, immunosuppression, and pregnancy.[1]

EPIDEMIOLOGY

Minimal information on the incidence and prevalence of VVC exists. Healthcare workers are not required to report cases of VVC; therefore, estimates are derived from self-reported histories. Epidemiologic data are limited because VVC usually is diagnosed without microscopy and/or cultures, and antifungal nonprescription preparations are available for self-treatment.[1] By 25 years of age, ~50% of college women will have had at least one episode of VVC.[1] It is rare before menarche and increases dramatically at about 20 years of age, with the peak incidence between age 30 and 40. It is associated with the initial act of sexual intercourse. As many as 75% of women experience one bout of symptomatic VVC in their lifetime. Between 40% and 50% of women who experience one episode of VVC experience a second episode, and 5% experience recurrent VVC.[2,3] Black women appear to be at higher risk than white women of developing VVC (62.8% vs 55%, respectively).[4] The incidence after menopause remains unknown.

Costs from VVC can be direct (medical visits and self-treatment) and indirect (nonmedical expenses, e.g., time losses from work, costs of travel, and time required in obtaining treatment). There are an estimated 6 million visits to healthcare providers each year, resulting in more than $1 billion spent annually on these medical visits and self-treatment.[5]

PATHOPHYSIOLOGY

2 *Candida albicans* is the major pathogen responsible for VVC, accounting for 80% to 92% of symptomatic episodes. The remainder are caused by non–*C. albicans* species, with *Candida glabrata* dominating.[6] The number of cases of non–*C. albicans* candidiasis appears to be increasing, possibly related to the use of nonprescription vaginal antifungal preparations and short-course therapy and/or the increased use of long-term maintenance therapy in preventing recurrent infections.[1]

Candida species can act as commensal members of the vaginal flora. Asymptomatic colonization with *Candida* species has been found in 10% to 20% of women of reproductive age.[6,7] *Candida* organisms are dimorphic; blastospores are believed to be responsible for colonization (transmission and spread), whereas germinated *Candida* forms are associated with tissue invasion and symptomatic infections.[8] To colonize the vagina, *Candida* species must be able to attach to the mucosa. The attachment process is complex. Not only are candidal surface structures important for attachment, but appropriate receptors for attachment must be present in the epithelial tissue. Not all women have the same range of receptors, which may explain variation in colonization.[7] Changes in the host's vaginal environment or response are necessary to induce a symptomatic infection. Unfortunately, in most cases of symptomatic VVC, no precipitating factor can be identified.[8]

RISK FACTORS

Several factors predispose a woman to VVC. VVC is not considered to be a sexually transmitted disease, although sexual factors can be important. There is a dramatic increase in the frequency of VVC when women become sexually active. In addition, oral-genital contact can increase the risk.[1] However, current guidelines do not recommend the treatment of asymptomatic partners.[6] Contraceptive agents, including the diaphragm with spermicide, the contraceptive sponge, and the intrauterine device, increase the risk of VVC. Oral contraceptive users demonstrated increased risk of candidiasis; however, these reports were with the higher-dose oral contraceptive pills, and the risk may not be as great with the lower-estrogen-dose oral contraceptives.[9]

Antibiotic use can increase the risk of VVC, but it is significant in only a small number of women. The mechanism by which antibiotics can increase the risk of VVC is unknown; colonization, however, is a prerequisite.[1] Diet (excess refined carbohydrates), douching, and tight-fitting clothing often are listed as important risk factors; however, no association has been established between these factors and increased risk of VVC.[1]

CLINICAL PRESENTATION

3 The clinical presentation of VVC is given in Table 129–1.[1,6] These signs and symptoms are not pathognomonic, and a reliable diagnosis cannot be made without laboratory tests. Self-diagnosis has a sensitivity of 35%, a specificity of 89%, and a positive predictive value of 62%.[4] More than 50% of women who had self-diagnosed VVC did not have yeast as the causative agent.[10] This limits the value of self-diagnosis and the success of self-treatment. The American College of Obstetricians and Gynecologists (ACOG) recommend that whenever possible women requesting treatment for VVC should be examined and evaluated. They only recommend self-diagnosis in compliant women with multiple confirmed prior cases of VVC who report the same symptoms. They further recommend that if these individuals fail to improve on a short course of therapy, they be evaluated for a further diagnosis.[11] Therefore, in most instances the diagnosis should be based on both clinical presentation and investigations, including vaginal pH, saline microscopy, and 10% potassium hydroxide (KOH) microscopy. The vaginal pH remains normal in VVC, and microscopic investigations should detect blastospores or pseudohyphae. *Candida* cultures usually are not required in the diagnosis of uncomplicated VVC; however, they are recommended when an individual presents with classic signs and symptoms of VVC, has a normal vaginal pH, but microscopy is inconclusive or recurrence is suspected.[6]

TABLE 129-1 Clinical Presentation of Vulvovaginal Candidiasis

General	Often involves both the vulva and the vagina
Symptoms	Intense vulvar itching, soreness, irritation, burning on urination, and dyspareunia
Signs	Erythema, fissuring, curdy "cheese"-like discharge, satellite lesions, edema
Laboratory tests	Vaginal pH–normal, saline and 10% KOH microscopy–blastospores or pseudohyphae
Other diagnostic tests	*Candida* cultures not recommended unless classic signs and symptoms with normal vaginal pH and microscopy are inconclusive or recurrence is suspected

KOH = potassium hydroxide.

TREATMENT

GOALS OF THERAPY

The goal of therapy is complete resolution of symptoms in patients who have symptomatic VVC. A test of the cure is not necessary if symptoms resolve.[6] Antimycotic agents used in the treatment of VVC do not meet the definition of being fungicidal agents because of their slower killing rate. At the end of therapy, the number of viable organisms drops below the detectable range. However, by 6 weeks after a course of therapy, 25% to 40% of women will have positive yeast cultures and remain asymptomatic.[1] Asymptomatic colonization with *Candida* species does not require therapy.

GENERAL APPROACHES TO TREATMENT

The approach to therapy is to remove or improve any predisposing factors if they can be identified. A pharmacologic agent should have limited local and systemic side effects, a high cure rate, and easy administration. Additionally, it would be advantageous to use a therapy that is able to resolve symptoms within 24 hours, that has broad antimycotic activity (to cover increasing rates on non–*C. albicans* species), that prevents recurrence, and that can be used over a shortened period of time, such as 1 to 3 days. Many topical azoles are available without a prescription, and although this may increase public access to these medications, there is concern that having them available without a prescription may lead to inappropriate use. A study conducted using 10 actors as simulated paients who visited 60 pharmacies found that vaginal antifungals were more likely to be supplied to appropriate individuals as more information was exchanged, if interactions involved a pharmacist, and if questions regarding specific symptoms were used.[12]

Patients should be advised to avoid harsh soaps and perfumes that can cause or worsen vulvar irritation. The genital area must be kept clean and dry by avoiding constrictive clothing and frequent or prolonged exposure to hot tub use.[3] Douching is not recommended for either prevention or treatment.[11] Cool baths can soothe the skin.[3] Daily ingestion of 240 mL yogurt containing *Lactobacillus acidophilus* has been shown to decrease colonization and symptomatic infections of VVC in women with recurrent infections.[13]

Treatment of VVC will be considered to have positive outcomes if the symptoms of VVC are resolved within 24 to 48 hours and no adverse medication events are experienced. Self-assessment of symptom relief is appropriate for most cases of VVC. If symptoms remain unresolved or recur, then further testing and treatment can be required.

PHARMACOLOGIC TREATMENTS

Uncomplicated Vulvovaginal Candidiasis

Cure rates for uncomplicated VVC are between 80% and 95% with topical or oral azoles and between 70% and 90% with nystatin preparations. Table 129–2 lists available topical and oral preparations for the treatment of uncomplicated VVC. There are many topical nonprescription preparations for the treatment of VVC. No significant differences in in vitro activity or clinical efficacy exist between the topical azole agents.[1,3,6,11] The selection of a topical azole should be based primarily on an individual patient's preference as to product formulation. Some topical products can cause vaginal burning, stinging, or irritation; conversely, the vehicle used in topical creams or gels can provide initial symptomatic relief.[1] Of note, most topical preparations can decrease the efficacy of latex condoms and diaphragms.

Oral azoles have been used in the treatment of VVC. Patients may prefer oral therapy because of its convenience.[14] Oral and topical therapy are therapeutically equivalent.[1] A Cochrane review of 19 trials analyzing 22 oral versus topical antifungal comparisons concluded that there were no differences between the routes in short-term mycologic cure rates. There was a significant difference between long-term cure rates in favor of long-term follow-up; however, the authors stated that the clinical significance of this finding is uncertain.[15]

TABLE 129-2 Treatment for Uncomplicated Vulvovaginal Candidiasis

Active Ingredient	Preparation	Regimen
Over-the-counter/topical vaginal products		
Butoconazole	2% cream	One applicator × 3 days
Clotrimazole	1% cream	One applicator × 1 day
	100 mg tablet	One 100 mg tablet × 7 days
	2% cream	One applicator × 1 day
	200 mg tablet	One 200 mg tablet × 3 days
	10% cream	One applicator × 1 day
	500 mg tablet	One 500 mg tablet × 1 day
Miconazole[a]	2% cream	One applicator × 1 day
	100 mg suppository	One 100 mg suppository × 7 days
	200 mg suppository	One 200 mg suppository × 3 days
	1200-mg ovule	One ovule × 1 day
Ticonazole	2% cream	One applicator × 3 days
	6.5% cream	One applicator × 1 day
Prescription/topical		
Nystatin	100,000-unit tablet	One tablet × 14 days
Terconazole	0.4% cream	One applicator × 7 days
	0.8% cream	One applicator × 3 days
Oral products		
Fluconazole	150 mg	One tablet × 1 day

[a]The FDA warns of the possible increase in the anticoagulant effects of warfarin with concomitant use.

In the treatment of uncomplicated VVC, the duration of therapy is not critical. Cure rates with different lengths of treatment have not demonstrated that one therapy is significantly better.[14,15,16] Shorter-duration therapies (e.g., clotrimazole 1-day therapy) consist of higher concentrations of azoles that maintain the local therapeutic effect for up to 72 hours and allow for resolution of signs and symptoms.[17] A review of 14 trials that examined 1-day treatments showed less than 7% difference in short-term cure rates or improvement between any two treatments in any two studies and no significant differences in short- or long-term clinical cure rates among 1-day regimens.[16] Table 129–2 lists the therapeutic options for the treatment of uncomplicated VVC.

Complicated Vulvovaginal Candidiasis

Complicated VVC occurs in patients who are immunocompromised or have uncontrolled diabetes mellitus.[1] These individuals need a more aggressive treatment plan.[11] Current recommendations are to lengthen therapy to 10 to 14 days regardless of the route of administration.[11] Therapeutic options include those listed in Table 129–2; however, regimens should be continued for 10 to 14 days. A study of oral fluconazole therapy in women with complicated VVC demonstrated that cure rates increased from 67% with single-dose therapy to 80% when the 150 mg dose of fluconazole was repeated 72 hours after the initial dose.[18]

VVC during pregnancy can be considered complicated because consideration of host factors such as hormonal changes that can affect normal flora are essential in selecting therapeutic regimens. Topical agents are considered to be safe throughout pregnancy. A systematic review of 10 trials demonstrated that imidazole topical agents were more effective than nystatin. Two of the trials showed that treatment for 7 days was more effective than treatments of 4 days or less.[19] Oral agents are contraindicated in pregnancy because of the concern for fetal complications. A prospective assessment of pregnancy outcomes in 226 women exposed to fluconazole in the first trimester did not indicate increased risk of congenital abnormalities or other adverse outcomes.[20] The median dose of fluconazole was 200 mg, with 46.5% of the cohort receiving a single dose of fluconazole 150 mg.[21] However, the ACOG recommends avoiding oral therapy, as larger doses of fluconazole have been linked to birth defects.[21] Instead, the ACOG recommends a topical imidazole therapy for 7 days.[11]

Recurrent Vulvovaginal Candidiasis

Recurrent vulvovaginal candidiasis (RVVC) is defined as having more than four episodes of VVC within a 12-month period.[1,6] Fewer than 5% of women develop RVVC, and its pathogenesis is poorly understood. A proper diagnosis should be obtained to rule out other infections or nonmycotic contact dermatitis. RVVC is best treated in two stages: an initial intensive stage followed by prolonged antifungal therapy to achieve mycologic remission. This was demonstrated in a randomized controlled trial in which women were assigned to receive 150 mg fluconazole daily for 10 days followed by 6 months of either fluconazole 150 mg weekly or placebo. Ninety percent of women receiving both active treatments were symptom free for the 6 months following initial treatment (during the weekly fluconazole therapy), and there were 50% fewer symptomatic episodes in the 6 months following weekly suppressive therapy.[22] The Infectious Diseases Society of America stated that there is good evidence from more than one properly randomized controlled trial to recommend 10 to 14 days of induction therapy with a topical or oral azole, followed by 150 mg of fluconazole once weekly for 6 months for recurring *Candida* VVC.[23]

CLINICAL CONTROVERSY

Self-diagnosis of VVC is unreliable; however, the availability of nonprescription antifungal agents encourages self-diagnosis and self-treatment for the majority of women. Therefore, women who self-treat should be monitored to ensure that the infection clears within a few days, or they need to see a physician for an accurate diagnosis.

Antifungal-Resistant Vulvovaginal Candidiasis

Resistance to azole antifungals should be considered in individuals who have persistently positive yeast cultures and fail to respond to therapy despite adherence to prescribed regimens.[1] These infections can be treated with boric acid or 5-flucytosine.[24,25] Boric acid is administered as a 600 mg intravaginal capsule daily for 14 days of induction therapy, followed by a maintenance regimen of one capsule intravaginally twice weekly. Boric acid should not be administered orally, as it is toxic. 5-Flucytosine cream is administered vaginally, 1,000 mg inserted nightly for 7 days. The prevalence of *C. glabrata* is higher in those with diabetes. In a study of 111 consecutive diabetic patients with VVC, 68% had isolates for *C. glabrata* compared with 28.8% for *C. albicans.* Those with *C. glabrata* had significantly higher mycological cure rates with 600 mg of boric acid suppositories for 14 days compared with a single dose of fluconazole 150 mg.[26]

OROPHARYNGEAL AND ESOPHAGEAL CANDIDIASIS

Oropharyngeal candidiasis (OPC), or *thrush,* refers to an infection of the oral mucosa. *Candida* is responsible for the majority of oral fungal infections, and *C. albicans* is the principal species causing the infection, commonly referred to as *candidiasis* (the proper but less commonly used term being *candidosis*). The infection may extend into the esophagus, causing esophageal candidiasis.

MICROBIOLOGY AND EPIDEMIOLOGY

Candida species are normal inhabitants of the human GI tract. They can be isolated from the oral cavity in up to 65% of healthy adults without producing any signs or symptoms.[27] This is referred to as *asymptomatic colonization.* The incidence of candidal carriage is increased under immunocompromised conditions, and the organism is capable of rapid conversion to a pathogen causing symptomatic mucosal infections. In HIV-infected individuals, asymptomatic colonization may be as high as 88%.[28] *C. albicans* is the predominant colonizing *Candida* species (70% to 80%), but any of the non–*C. albicans* species can be colonizers. Colonization rates are influenced by the severity and nature of the underlying medical illness and the duration of hospitalization, as well as age (highest in infants younger than 18 months of age and in adults older than 60 years of age). A variety of host and exogenous factors (Table 129–3) can lead to the transformation of asymptomatic colonization to symptomatic disease, such as oropharyngeal and esophageal candidiasis. *C. albicans* is the most common species causing all forms of mucosal candidiasis in humans. Less frequently, non–*C. albicans* species can be pathogenic and cause disease. These include *C. glabrata, Candida tropicalis, Candida krusei, Candida guilliermondii,* and *Candida parapsilosis.*[29,30] *C. krusei,* although relatively uncommon, generally is recovered from mucosal surfaces of neutropenic patients with hematologic malignancies.[29] Another species, *Candida dubliniesis,* has been identified in both HIV-infected and -noninfected patients, and may cause ~15% of infections previously ascribed to *C. albicans.*[29] In patients with cancer, non–C. *albicans* species account for almost half of all *Candida* infections.

Oropharyngeal candidiasis is the most common opportunistic infection in patients with HIV disease, and it may be the first clinical manifestation of the HIV infection in the majority of untreated patients. OPC occurs in 50% to 90% of HIV-infected patients at some point during the progressive course of the disease to acquired immunodeficiency syndrome (AIDS),[27,28,30] although significant reductions in the incidence have been observed after the introduction of highly active antiretroviral therapy (HAART). The incidence of OPC increases as the level of immunity decreases, especially when the CD4 T-cell counts are between 500 and 200 cells/mm^3 and is further increased when the CD4 T-cell counts drop below 200 cells/mm^3.[27] OPC is considered one of the earliest indicators of HIV infection and is a relatively reliable indirect marker of disease progression. Regardless of the CD4 T-cell count, OPC is predictive for the development of AIDS-related illnesses if left untreated.[27,30] In non-HIV diseases, such as cancer, the incidence of OPC varies depending on the type of malignant neoplastic disease, level of immune suppression, and type and duration of treatment, but it is less common than in HIV-infected patients. OPC was initially reported in ~25% of patients with solid tumors and up to 60% in those with hematologic malignancies or bone marrow transplant recipients.[31] Current rates of OPC have decreased significantly in these patients because of widespread use of antifungal prophylaxis.

OPC can predispose patients to develop more invasive disease, including esophageal candidiasis.[30] The esophagus is the second most common site of GI candidiasis. The prevalence of esophageal candidiasis has increased mainly because of the number of individuals with AIDS, as well as the increased numbers of other severely immunocompromised patients, especially those with hematologic malignancies.[29] Esophageal candidiasis is the first opportunistic infection in 3% to 10% of HIV-infected patients and is the second most common AIDS-defining disease after *Pneumocystis jiroveci* pneumonia.[30] The mean incidence of esophageal candidiasis among HIV-infected patients is less than OPC and ranges from 15% to 20%.[30] The risk of esophageal candidiasis is increased in HIV-infected patients when the CD4 T-cell count has dropped below 100 to 200 cells/mm^3, as well as in those with OPC.[32,33] However, the absence of OPC does not necessarily exclude the possibility of esophageal disease. Like OPC, the presence of esophageal candidiasis can help predict HIV disease progression and prognosis.[30] The incidence of esophageal candidiasis in non-HIV-infected immunocompromised patients is not well established. *C. albicans* is the most common cause of esophageal candidiasis, accounting for ~80% of cases, with the rest being caused by non–*C. albicans* species.[29,30]

The epidemiology of mucosal candidiasis has been affected by two factors. The introduction of HAART appears to have resulted in a significant decline in the incidence of OPC and esophageal candidiasis.[27,28] This is postulated to be caused both by enhanced immune responsiveness and by direct action on the organism by HAART.[28] The widespread use of the azole agents has led to a decline in the prevalence of mucosal candidiasis while leading to the emergence of refractory infections that have become difficult to treat.

PATHOGENESIS AND HOST DEFENSES

The pathogenesis of OPC is most clearly elucidated in the setting of HIV infection. There appear to be several levels of immune defense against the development of OPC in HIV-infected persons, and they involve both systemic and local immunity. The primary line of host defense against *C. albicans* is cell-mediated immunity (CMI) at the mucosal surfaces, which is mediated by CD4 T cells.[27] The efficacy of the CD4 T cells is reduced when the number of cells drops below

TABLE 129-3 Risk Factors for the Development of Oropharyngeal and/or Esophageal Candidiasis

Local factors	Potential mechanisms
Use of steroids and antibiotics	Suppression of cellular immunity and inhibition of phagocytosis by steroids, including chronic use of inhaled and topical steroids
	Alteration of endogenous oral flora by broad-spectrum antibiotics, especially when used with steroids, creates a milieu for proliferation of *Candida* species because of reduced environmental and nutritional competition
Dentures	Enhanced adherence of *Candida* species to the acrylic material of dentures, reduced saliva flow under surfaces of denture fittings, improperly fitted dentures, and poor oral hygiene provide a milieu conducive to the survival of microorganisms
Xerostomia caused by drugs (e.g., tricyclic antidepressants and phenothiazine), chemotherapy, radiotherapy to the head/neck, and various diseases (e.g., Sjögren syndrome, HIV, and cancer of the head/neck), as well as bone marrow transplant recipients	Reduced dilutional and cleansing effect caused by low secretion rate and low pH in saliva: saliva and mucosa secretions have defense factors, such as lactoferrin, sialoperoxidase, isozyme, histidine-rich polypeptide, secretory IgA antibodies, specific anti-*Candida* antibodies that help prevent adhesion and overgrowth of *Candida* species
Smoking	
Disruption of oral mucosa caused by chemotherapy and radiotherapy, ulcers, endotracheal intubation trauma, and burns	Oral mucositis induced by radiation and breaks in the physical barrier of the oral epithelium, which is protective against invasion by microorganisms; altered rate of mucosa regeneration by cancer chemotherapy, which increases vulnerability to infection.
Systemic factors	**Potential mechanisms**
Drugs (e.g., cytotoxic agents, corticosteroids, and immunosuppressants after organ transplant), omeprazole, and environmental chemicals (e.g., benzene and pesticides)	Reduced immunity because of drug-induced neutropenia or cell-mediated immunity; potent inhibition of gastric acid by PPIs can facilitate the growth of *Candida* species; PPIs also can inhibit the cytotoxic effect of lymphocytes and reduce salivary secretion
Neonates or the elderly	Immature immune system of neonates who usually acquire infection during birth to a mother with vaginal candidiasis or from exposure to infected bottle nipples or to skin of adult caregiver
	Elderly—unclear if this is the direct effect of age per se or contribution from dentures or underlying comorbidity
HIV infection/AIDS	Depletion of CD4 T lymphocytes especially below 200–300 cells/mm^3; anti-*Candida* protective mechanism of T lymphocytes at a mucosal level is unclear but can be caused by altered cytokines, especially interferon-γ, that inhibit transformation of *Candida* blastoconidia to the more invasive hyphal phase
Diabetes	Higher than normal numbers of *Candida albicans* cultured from saliva of diabetic patients; can be related to the elevated glucose levels and reduced chemotactic factor in saliva, altered neutrophil function, and reduced saliva volume and flow
Malignancies (e.g., leukemia and head/neck cancer)	Use of intensive radiotherapy and chemotherapy can disrupt oral mucosa and cause xerostomia; prolonged use of broad-spectrum antibiotics in neutropenic patients can alter the normal oral flora; because of the prolonged neutropenia, the principal immune defect, seen especially in leukemic patients, the initial oropharyngeal candidiasis can become systemic or invasive
Nutritional deficiencies (e.g., iron, folate, and vitamins B_1, B_2, B_6, B_{12}, and C)	Can be related to dietary restriction or GI absorption problems; deficiencies can serve to enhance the pathogenic potential of the *Candida* inhabitants, alter host defense mechanisms, or change epithelial barrier integrity

AIDs = aquired immunodeficiency syndrome, GI = gastrointestinal, HIV = human immunodeficiency virus, IgA = immunoglobulin A, PPI = proton pump inhibitor.

a protective threshold, and protection against infection becomes dependent on secondary or local immune mechanisms.[27,28] When the number of CD4 T cells drops too low, recruitment of these cells to the oral cavity is impaired. The CD4 T-cell count has been considered as the hallmark predictor for development of OPC. However, HIV viral load may have a stronger association with OPC than CD4 cell number.[34] This requires further confirmation by larger cohort studies. The possibility that HIV plays a strong role in susceptibility to infection is supported clinically by the observation that OPC is more common in HIV-infected persons than in those with similar immunosuppression, such as lymphoma and bone marrow transplant. When the primary line of defense fails, the secondary host defenses become crucial. These include the CD8 T cells, salivary cytokines, and other innate immune cells, such as the neutrophils, macrophages, and epithelial cells (with anti-*Candida* activity). Deficiencies or dysfunction in any of these can result in susceptibility to OPC. The problem with the CD8 T cells is caused more by a dysfunction of the microenvironment, specifically, reduction in the E-cadherin adhesion molecule that promotes migration of the cells through mucosal tissues.[28] The role of humoral immunity by antibodies as a protective mechanism is unclear and controversial. The changeover of the role of *Candida* species from commensal to pathogenic in the human host usually occurs when breakdown in these host defenses occurs. The pathogenesis of OPC is still not completely understood. It is important to develop a better understanding of the pathogenesis and role of host defenses, including the mechanism of CD8 T-cell activity, reduced adhesion molecules, and whether other cofactors, such as HIV viral load, HAART, and injection drug use (IDU), play a role. Immunotherapeutic modalities can then be developed to eliminate the susceptibility factors and significantly reduce OPC in the at-risk populations.

Significant differences exist in the virulence among *Candida* species in mucosal candidiasis. One virulence factor is the ability of the organism to adapt and survive in response to changes in the host environment.[29] The genes required for virulence are regulated in response to the environmental signals indigenous to the host environment (e.g., temperature, pH, osmotic pressure, iron and calcium ion concentrations, oxygenation, and carbon and nitrogen availability). The ability of *C. albicans* to undergo reversible morphologic transition between the budding pseudohyphal and the more invasive hyphal growth forms is also a determinant of virulence, and genes are recognized to play a role.[29] Other virulence factors are the adhesive ability of *C. albicans* to epithelial cells and proteins and its ability to invade host cells by means of phospholipase and proteinase enzymes. This may be one of the factors leading to OPC in non-HIV-infected individuals. Other components of the pathogenesis in the absence of HIV that have been postulated are the ability of the *Candida* species to adhere to buccal epithelial cells. A close correlation between adhesion of *Candida* species and their ability to cause infection has been demonstrated in animal model studies.[35] This is hypothesized to be a key element in the development of OPC in patients with altered microflora, including those receiving broad-spectrum antimicrobial therapy.

TABLE 129-4 Clinical Classification of Oropharyngeal Candidiasis

Types	Population at Risk	Clinical Signs and Appearance
Pseudomembranous (thrush)	Neonates, patients with HIV or cancer, the debilitated elderly, patients on broad-spectrum antibiotics or steroid inhalers, patients with dry mouth from various causes, and smokers	Classic "cottage cheese" appearance, yellowish white, soft plaques (or milk curds) overlying areas of erythema on the buccal mucosa, tongue, gums, and throat; plaques are easily removed by vigorous rubbing but can leave red or bleeding sites when removed; lesions on the tongue dorsum give it a bald, depapillated appearance
Erythematous (acute atrophic)	Patients with HIV, patients on broad-spectrum antibiotics or steroid inhalers	Sensitive and painful erythematous mucosa with few, if any, white plaques; lesions are generally on the dorsal surface of the tongue or the hard palate, occasionally on the soft palate, but any part of the mucosa can be involved; appear as flat red patches on the palate or atrophic patches on the tongue dorsum with loss of papillae
Hyperplastic (candidal leukoplakia)	Smokers; uncommon in patients with HIV	Thick white and adherent keratotic plaques commonly seen on the buccal mucosa and lateral border of the tongue; can also be seen on the lips and the bottom of the mouth; plaques cannot be easily scraped off or only partially removed; this condition is distinct from oral hairy leukoplakia, and it can progress to severe dysplasia or malignancy
Angular cheilitis	Patients with HIV, denture wearers	Painful red, ulcerative, cracking, or fissuring lesion at one or both comers of the mouth because of an inflammatory reaction; usually lesions are small and rather punctate, but occasionally they can extend in a linear fashion from the angles onto the facial skin
Denture stomatitis (chronic atrophic)	Denture wearers who tend to be elderly and have poor oral hygiene	Red, flat lesions on the mucosa beneath the denture and extend right up to the denture border; more commonly located beneath a maxillary denture, although they can be encountered beneath a mandibular denture

HIV = human immunodeficiency virus.

RISK FACTORS

4 Several host and exogenous factors contribute to the ability of *Candida* species to cause infection (see Table 129–3). Local and systemic factors, as well as characteristics of the organism itself, can increase the susceptibility of an individual to *Candida* infections.[27,29,31] Endocrine disorders besides diabetes mellitus, such as hypothyroidism, hypoparathyroidism, and hypoadrenalism, also can predispose patients to *Candida* species overgrowth. Patients with primary immune deficiencies such as lymphocytic abnormalities, phagocytic dysfunction, immunoglobulin A (IgA) deficiency, viral-induced immune paralysis, and severe congenital immunodeficiencies are also at risk for oropharyngeal candidiasis as well as disseminated candidiasis. Oral mucosal disease, such as lichen planus, can be preexistent causes of candidiasis. Smoking has been suggested as a predisposing risk factor. In many cases, multiple concurrent predisposing factors to candidiasis can exist, for example, xerostomia with mucositis and a break in the epithelial surface or immunosuppression, such as might occur in a leukemic patient receiving radiation and chemotherapy. The severity and extent of *Candida* infections increase with the number and severity of predisposing risk factors.

CLINICAL PRESENTATION AND DIAGNOSIS

Oropharyngeal candidiasis can manifest in several major forms (Table 129–4).[27,29,31] The clinical signs and symptoms of OPC and the locations of the lesions can be quite diverse (Table 129–5). A presumptive diagnosis of OPC usually is made by the characteristic appearance on the oral mucosa, with resolution of signs and symptoms after antifungal therapy. Pseudomembranous candidiasis, commonly known as *oral thrush*, is the classic and most common

TABLE 129-5 Clinical Presentation of Oropharyngeal and Esophageal Candidiasis

Oropharyngeal Candidiasis

General

The clinical features can be quite diverse (see Table 129–4)

Symptoms

Symptoms are diverse and range from none to sore, painful mouth, burning tongue, metallic taste, and dysphagia and odynophagia with involvement of the hypopharynx

Signs

Signs are variable and can include diffuse erythema and white patches on the surfaces of the buccal mucosa, throat, tongue, or gums; constitutional signs are absent

Laboratory tests

Scraping of an active lesion for microscopic examination can help confirm the diagnosis (presence of pseudohyphae and budding yeast) but is usually not necessary

Cultures are not necessary because isolation of *Candida* species does not distinguish between colonization and true infection; cultures can be taken in patients responding poorly to therapy to determine the infecting species and to predict likely drug resistance

Esophageal Candidiasis

General

This usually occurs as an extension of OPC; however, the esophagus can be the only site involved; the distal two-thirds, rather than the proximal one-third, is the most common site

Symptoms

Typically, the symptoms are dysphagia, odynophagia, and retrosternal chest pain but can be asymptomatic in some patients; although rare, epigastric pain can be the dominant symptom

Signs

Constitutional signs, including fever, occasionally occur; physical findings can range from a few to numerous white or beige plaques of variable size

Plaques can be hyperemic or edematous, with ulceration in more severe cases

Most advanced cases can occur with increased mucosal friability and narrowing of lumen

Uncommon complications include perforation and aortic–esophageal fistula formation

Laboratory tests

The best test is upper GI endoscopy (more useful than barium swallow); helps exclude other causes of esophagitis (e.g., viral, aphthous ulcers); diagnosis is confirmed by the histologic presence of *Candida* species in biopsy lesions taken during endoscopy

Cultures to look for drug-resistant *Candida* species are warranted in patients who require endoscopy

GI = gastrointestinal, OPC = oropharyngeal candidiasis.

form seen in immunosuppressed and immunocompetent hosts. Erythematous and hyperplastic candidiasis and angular cheilitis occur less commonly in the HIV-infected population. Dysphagia, odynophagia, and retrosternal chest pain are common complaints of esophageal candidiasis, which is usually, but not always, accompanied by the presence of OPC. Clinical symptomatology, along with a therapeutic trial of antifungal, can provide a reliable presumptive diagnosis of esophageal candidiasis. If antifungal therapy does not lead to resolution, more invasive tests such as upper GI endoscopy can be undertaken.

TREATMENT

Oropharyngeal and Esophageal Candidiasis

DESIRED OUTCOMES

The primary desired outcome in the management of OPC is a clinical cure, that is, elimination of clinical signs and symptoms. Even when the patient is relatively asymptomatic, it is important to treat the initial episode of OPC to avoid progression to more extensive disease. In the most severe cases, the patient's quality of life can be impaired; this can result in decreased fluid and nutritional intake. Lack of appropriate treatment of OPC can lead to more extensive oral disease, especially in patients who are immunocompromised. The most serious complication of untreated OPC is extension of the infection to esophageal candidiasis. Because esophageal candidiasis is more debilitating, the patient's quality of life is more affected. It is important to initiate appropriate antifungal therapy for both OPC and esophageal candidiasis. Preventing or minimizing the number of future recurrences of both types of candidiasis is an equally important outcome. The approach depends largely on the underlying predisposing conditions. Mycologic cure is not a necessary treatment outcome because it may not be feasible or realistic, given that *Candida* species exist commonly as part of the normal mouth flora.

Minimizing toxicities and drug–drug interactions of systemic antifungal agents, as well as maximizing adherence by ensuring that the patient understands the importance of therapy and the directions to take the medication appropriately, are important secondary outcomes of therapy.

GENERAL APPROACH TO TREATMENT

The management of OPC should be individualized for each patient, taking into consideration the underlying immune status, other concurrent mucosal and medical diseases, concomitant medications, and exogenous infectious sources. In HIV-infected patients with inadequately controlled disease, antifungal treatment produces only a transient clinical response, and the relapse rates are higher than in other patient populations. These patients usually require frequent courses of antifungal treatment. Therefore, in patients with HIV disease, treatment with effective HAART is paramount because this would provide the best prophylaxis against recolonization and recurrence of symptoms.[29,31,33]

Whenever feasible, it is desirable to minimize all predisposing factors, such as administration of corticosteroids, chemotherapeutic agents, and antimicrobials, as well as institute proper oral hygiene and resolve concurrent conditions, such as denture stomatitis. Selection of an appropriate antifungal agent for treatment of candidiasis requires consideration of several factors, including the patient's drug adherence, adequate saliva for dissolution of solid topical medications, risk of caries from sucrose- or dextrose-containing preparations, potential drug interactions, coexisting medical conditions (e.g., liver disease), location and severity of the infection, and the need for long-term maintenance therapy. Another factor that could affect drug selection is overuse of fluconazole, leading to the emergence of fluconazole-resistant species of *C. albicans,* and in some cases to all azoles, and other intrinsically more resistant species, such as *C. krusei, C. glabrata,* and *C. tropicalis.*

5 Topical therapies should be the first choice for milder forms of infections.[37] The efficacy of antifungal agents for OPC varies in different patient populations. Until the polyene antifungal agents became available in the 1950s, gentian violet, an aniline dye, was used to treat OPC. Problems with gentian violet include fungal resistance, skin irritation, and especially the unaesthetic staining of the oral mucosa. Topical agents, such as nystatin and clotrimazole, have been the standard of treatment for uncomplicated OPC and generally are effective for treatment in otherwise healthy adults and infants with no underlying immunodeficiencies. Topical agents are available in an assortment of formulations, including oral rinses (suspension), troches, powder, vaginal tablets, and creams. The two most common types of formulations currently used are suspension and troches (Table 129–6).

Topical agents require frequent applications because of the short contact time with the oral mucosa; the ideal contact time is 20 to 30 minutes. Sufficient saliva is needed to dissolve clotrimazole troches, and this can be problematic for patients with xerostomia. Also, the rough surface of the tablet can become irritating to the oral soft tissue. Troches also contain dextrose, which has cariogenic potential. Nystatin suspension might be a better choice for patients with xerostomia, but it is difficult to maintain adequate contact time with the oral mucosa. Some patients complain of the unpleasant taste of nystatin, which can cause nausea and vomiting; this is especially problematic in cancer patients experiencing chemotherapy-induced nausea. The high sucrose content of nystatin suspension is cariogenic in dentate patients, and it should be used with caution in diabetic patients. Topical creams, such as clotrimazole, ketoconazole, miconazole, and nystatin (usually mixed with a steroid), are more appropriate for application three times daily to the corners of the mouth in treating angular cheilitis.[38]

Systemic therapy is necessary in patients with OPC that is refractory to topical treatment, those who cannot tolerate topical agents, moderate to severe disease, and those at high risk for disseminated systemic or invasive candidiasis. Effective treatment of esophageal candidiasis generally requires the use of systemic antifungal agents. However, these agents have the disadvantage of producing more side effects (see Table 129–6) and drug–drug interactions (see Chapter 130). Fluconazole is inexpensive and generally well tolerated, and its absorption is unaffected by food or gastric acidity. Ketoconazole requires gastric acidity for absorption, which can be problematic in AIDS patients with achlorhydria; hence, it is best given with an acidic beverage. It is not recommended today with the availability of more effective triazoles. Itraconazole capsules also have the same absorption problem and are no longer recommended. In contrast, itraconazole solution has enhanced absorption and is best taken in a fasting state; in addition, the solution provides the benefit of both topical effects to the oral mucosa and systemic effects and is beneficial to patients with mucositis or swallowing problems. Whenever possible, it is generally beneficial to limit the use of systemic azole agents to prevent unnecessary drug exposure and to minimize the potential for occurrence of drug-resistant candidiasis, particularly from fluconazole resistance.

When patients become unresponsive to topical agents or fluconazole and itraconazole, alternative agents are available.[32,33,37] These include amphotericin B and newer triazoles (voriconazole and

TABLE 129-6 Therapeutic Options for Mucosal Candidiasis

Initial episodes of OPC:[a] Treat for 7–14 days	**Common/significant side effects**
Clotrimazole 10 mg troche: hold 1 troche in mouth for 15–20 minutes for slow dissolution 5 times daily (B-2)	Altered taste, mild nausea, vomiting
Nystatin 100,000 units/mL suspension: 5 mL swish and swallow 4 times daily (B-2)	Mild nausea, vomiting, diarrhea
Fluconazole100 mg tablets:[b] 100–200 mg daily (A-1)	GI upset, hepatitis not common
Itraconazole 10 mg/mL solution:[c] 200 mg daily (A-2)	GI upset, not common: hepatotoxicity, CHF, pulmonary edema with long-term use[e]
Posaconazole 40 mg/mL suspension: 400 mg daily with a full meal (A-2)	GI upset, fever, headache, increased hepatic transaminases not common
Fluconazole-refractory OPC: Treat for ≥ 14 days	**Common/significant side effects**
Itraconazole 10 mg/mL solution: 200 mg daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg twice daily (>40 kg), taken on empty stomach (A-3)	GI upset, rash, reversible visual disturbance (altered light perception, photopsia, chromatopsia, photophobia), increased hepatic transaminases, hallucinations, or confusion
Posaconazole 40 mg/mL suspension: 400 mg twice daily × 3 days, then 400 mg daily × 28 days (A-2)	See above
Amphotericin B 100 mg/mL suspension:[d] 1–5 mL swish and swallow 4 times daily (B-2)	Oral: nausea, vomiting, diarrhea with higher dose
Amphotericin B deoxycholate 50 mg injection: 0.3–0.7 mg/kg/day IV daily (B-2)	IV: fever, chills, sweats, nephrotoxicity, electrolyte disturbances, bone marrow suppression
Caspofungin 50 mg IV daily (B-2)	Fever, headache, infusion-related reactions (<5%) (e.g., rash, facial swelling, pruritus, vasodilation), hypokalemia, increased hepatic transaminases, anemia, neutropenia
Micafungin 150 mg IV daily (B-2)	Similar to caspofungin
Anidulafungin 200 mg IV daily (B-2)	Similar to caspofungin
Esophageal candidiasis:[a] Treat for 14–21 days	**Common/significant side effects**
Fluconazole 100 mg tablets: 200–400 mg (3–6 mg/kg) daily (A-1)	See above
Echinocandin: see above (B-2)	See above
Amphotericin B deoxycholate 50 mg injection: 0.3–0.7 mg/kg/day IV daily (B-2)	See above
Posaconazole 40 mg/mL suspension: 400 mg twice daily (A-3)	See above
Itraconazole 10 mg/mL solution:[c] 200 mg daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg twice daily (>40 kg) (A-3)	See above
Voriconazole and echinocandins (A-1): generally reserved for refractory cases	See above
Fluconazole-refractory EC: Treat for 21–28 days	**Common/significant side effects**
Itraconazole 10 mg/mL solution: 200 mg daily. (A-2)	See above
Posaconazole 40 mg/mL suspension: 400 mg twice daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg twice daily (>40 kg), taken on empty stomach (A-3)	See above
Caspofungin 50 mg IV daily (B-2)	See above
Micafungin 150 mg IV daily (B-2)	Similar to caspofungin
Anidulafungin 100 mg IV on day 1, then 50 mg IV daily (B-2)	Similar to caspofungin
Amphotericin B deoxycholate: 0.3–0.7 mg/kg/day IV, or lipid-based amphotericin 3–5 mg/kg/day IV (B-2)	See above

CHF = congestive heart failure, GI = gastrointestinal, IV = intravenous.

[a]Initial episodes of OPC can be adequately treated first with topical agents before resorting to systemic therapy (B-2), but systemic therapy is required for effective treatment of esophageal candidiasis. (A-2) Suppressive therapy is recommended for patients with frequent or severe recurrences (A-1).

[b]Fluconazole is more effective than ketoconazole (A-1).

[c]Solution is more effective than capsule (A-1); solution is better taken on an empty stomach.

[d]Suspension is not marketed; can be prepared extemporaneously by pharmacy.[50]

[e]See discussion under onychomycosis.

Recommendation grades:

Strength of recommendation: **A**–Both strong evidence for efficacy and substantial clinical benefit to support recommendation for use. *Should always be offered*. **B**–Moderate evidence for efficacy but only limited clinical benefit, to support recommendation for use. *Should generally be offered*. **C**–Evidence for efficacy is insufficient to support recommendation for or against use; or evidence for efficacy might not outweigh adverse consequences or cost of the treatment under consideration. *Optional*. **D**–Moderate evidence for lack of efficacy or adverse outcome supports a recommendation against use. *Should generally not be offered.*

Quality of evidence: **1**–Evidence from at least one properly designed randomized, controlled trial. **2**–Evidence from at least one well-designed trial without randomization, from cohort or case-controlled analytic studies (preferably from more than one center), or from multiple time-series studies, or dramatic results from uncontrolled experiments. **3**–Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees. (UR) Evidence currently unrated.

posaconazole) and echinocandins (caspofungin, micafungin, and anidulafungin) (see discussion below).

Oropharyngeal Candidiasis: HIV-Infected Patients

It is appropriate to start therapy with topical agents for initial or recurrent episodes of OPC, provided that clinical symptoms are not severe and that there is minimal risk of esophageal involvement.[32,37] Clinical responses with the resolution of signs and symptoms generally occur within 5 to 7 days of initiating treatment. Clotrimazole appears to be the most effective topical agent and demonstrates comparable clinical response rates with both fluconazole and itraconazole.[30,33] However, topical therapy is associated with more frequent relapses than with fluconazole.[32,33] This may be of limited clinical significance in patients receiving effective HAART because of their decreased susceptibility to opportunistic infection. In practice, nystatin suspension is still used frequently in initial episodes of OPC, although it is the least effective agent and is associated with frequent treatment failures and early relapses, especially in patients with advanced HIV disease or neutropenia.[30,33]

Systemic oral azoles should be reserved for use in the more severe episodes of OPC unresponsive to topical agents or in patients with concurrent esophageal involvement.[30,32,33] In clinical practice, fluconazole usually is the systemic azole agent of choice because of its

proven efficacy, favorable absorption, safety, and drug-interaction profiles, and it is relatively inexpensive. Fluconazole is superior to ketoconazole and itraconazole capsules.[30,32,33] Current guidelines suggest a regimen of 100 to 200 mg/day for 7 to 14 days.[37] There is evidence from one study showing a single dose of fluconazole 750 mg orally is as effective as fluconazole 150 mg orally for 14 days, which warrants further evaluation, given the potential advantages of adherence and cost-effectiveness.[38] Itraconazole oral solution with an improved absorption profile compared with the capsule formulation is as effective as fluconazole, with comparable clinical and mycologic response and relapse rates.[30,32,33] However, it carries a higher risk of drug interactions because it is a potent inhibitor of the cytochrome P450 enzymes, and it is associated with more nausea than fluconazole. Posaconazole is a new extended-spectrum triazole with potent in vitro activity against both *C. albicans* and non–*C. albicans* species. It is equivalent to fluconazole in terms of efficacy, safety, and tolerability.[37] Posaconazole has joined itraconazole solution and voriconazole as the azole alternatives to fluconazole in the management of moderate to severe OPC. Other agents that are effective are amphotericin B and the echinocandins (caspofungin, micafungin, and anidulafungin). They are better reserved for refractory OPC, however, because of their greater toxicity. They are also more expensive and are less convenient to use.

Oropharyngeal Candidiasis: Non-HIV-Infected Patients

This patient population includes patients with hematologic malignancy (e.g., leukemias) or blood and marrow transplantation (BMT) with a long duration of neutropenia and chronic graft-versus-host disease, patients with solid tumors, patients with solid-organ transplants who are receiving immunosuppressive therapy, and patients with diabetes mellitus, as well as patients on prolonged courses of antibiotics or corticosteroids and the debilitated elderly. Factors to consider in deciding whether to use topical or systemic antifungal therapy include the severity and extent of mucosal involvement (oropharyngeal vs esophageal), predisposing risk factors, and risk for dissemination. Patients who develop neutropenia (e.g., leukemic and BMT patients) are usually at high risk for disseminated and invasive fungal disease, and treatment of oral candidiasis is more aggressive. Patients with cell-mediated immune deficits but normal or near-normal granulocyte function and number (e.g., solid tumors, solid-organ transplants, or diabetic patients) are at low risk for dissemination of infection.

Specific antifungal therapy can be unnecessary for asymptomatic patients at relatively low risk for disseminated candidiasis, such as those who are not granulocytopenic or who are expected to have a short duration of granulocytopenia.[39] Many of these infections will clear spontaneously after recovery of the granulocytes or discontinuation of antibiotic and/or immunosuppressive therapy. However, antifungal therapy usually is required for patients who have persistent infection or significant symptoms, usually pain, or who are granulocytopenic with a relatively high risk of fungal dissemination. Topical agents first can be given a therapeutic trial depending on the severity of infection and the degree of immunosuppression. Although both nystatin and clotrimazole can be effective in treating OPC, nystatin suspension does not effectively reduce the incidence of either oropharyngeal or systemic *Candida* infections in immunocompromised patients receiving chemotherapy or radiation; its use often is associated with treatment failures and early relapses.[39,40] Clotrimazole appears to be more effective in reducing colonization and treating acute episodes in cancer patients who are immunocompromised.

Systemic azole agents are used for treating OPC in patients who have failed or who are unable to take topical therapy.[33,39] The preceding discussion on the relative efficacy of fluconazole, itraconazole, and ketoconazole in HIV-infected patients can be extrapolated to the non-HIV-infected population. Fluconazole 100 to 200 mg daily is used more commonly because of more extensive experience with its use, and it is more effective and has a more favorable absorption and side effect profile compared with other available azoles.[30] If the oral route is not feasible for reasons such as severe chemotherapy-induced mucositis, fluconazole can be administered intravenously. In patients unresponsive to azoles, IV amphotericin B in relatively low doses of 0.1 to 0.3 mg/kg/day can be tried.[39] Because of the higher risk for dissemination in patients who are severely neutropenic ($<0.1 \times 10^9$ neutrophils/L) or clinically unstable (hypotensive or febrile), some clinicians prefer to initiate therapy with IV amphotericin B at 0.6 mg/kg/day, with therapy continued until the neutropenia has resolved.[39] The echinocandins caspofungin, micafungin, and anidulafungin have all been studied for the treatment of OPC and found to be effective, thus offering another option in the patient with refractory disease.[37]

Topical therapy with clotrimazole or nystatin for 7 days is usually adequate for treating mucocutaneous candidiasis in most solid-organ transplant patients.[36] Use of topical therapy will reduce the number of systemic drugs that these patients receive and hence minimize the risk of drug–drug interactions. Failure to respond to topical agents warrants the use of fluconazole. Low-dose amphotericin B solution as swish and swallow (100 mg/mL, 1 mL four times daily) for 7 to 10 days is reserved for the unusual cases of treatment failure.

Patients who develop OPC because of prolonged antibiotic use or aerosolized corticosteroids use can be managed successfully by discontinuation of the offending agent, and the infection usually will resolve. If there is a strong desire to treat because of discomfort or need to hasten symptom resolution or an inability to stop the offending agent, therapy with a topical agent, either clotrimazole or nystatin, is effective in most cases. The advantage of systemic azoles is the convenience of less frequent dosing. Symptoms usually improve in 3 or 4 days. Infants should be given smaller amounts more frequently (e.g., nystatin 100,000 units every 2–3 hours) to ensure better contact time. For denture-related OPC, or candidal stomatitis, effective therapy requires treatment of both the mouth and the dentures to avoid relapse. The dentures must be brushed vigorously and disinfected every night by soaking in antiseptic solution, such as chlorhexidine gluconate 0.25% or a product such as Polident or Efferdent.[31,33] Topical antifungal therapy of the oral cavity is required. Consistent proper oral hygiene and care of the dentures can help prevent relapse.

Esophageal Candidiasis: HIV-Infected Patients

6 Treatment of esophageal candidiasis has not been as well studied as OPC. Because of the significant morbidity of esophageal candidiasis and the absence of evidence supporting the efficacy of topical antifungals, treatment requires systemic antifungal agents.[32,33,37] Fluconazole is superior to ketoconazole and itraconazole capsules with respect to endoscopic cure and clinical response and usually produces a more rapid onset of action and resolution of symptoms.[30,32,33,37] Fluconazole is as effective as itraconazole solution, with reported response rates of >80% to 90%.[33] However itraconazole solution causes more nausea and drug interactions because of inhibition of the cytochrome P450 enzymes. Amphotericin B, voriconazole, posaconazole, and the echinocandins are also effective in esophageal candidiasis, but they are generally reserved for patients with advanced or inadequately controlled HIV disease where the candidiasis tends to recur or becomes refractory to azole therapy.[43–46]

Esophageal Candidiasis: Non–HIV-Infected Patients

As in the case of HIV-infected patients, treatment of esophageal candidiasis requires systemic therapy. Patients can be started on fluconazole 200 to 400 mg/day for 14 to 21 days.[37] Higher fluconazole doses (up to 400 mg/day) have been suggested for patients with severe symptoms or those who are neutropenic.[36] Other agents currently recommended if fluconazole is not an option are an echinocandin or amphotericin B at 0.3 to 0.7 mg/kg. Itraconazole solution, posaconazole, and voriconazole are effective alternatives that may be considered for those not responding adequately to fluconazole. An echinocandin or IV amphotericin B may be selected over fluconazole for initial therapy in neutropenic patients who present with severe symptoms or who are at high risk for dissemination of *Candida* species, such as those receiving other aggressive immunosuppressive therapy (e.g., corticosteroids, total-body irradiation, or antithymocyte globulin) and who have documented evidence of esophageal candidiasis or who have failed an initial empirical trial of oral nonabsorbable agents or systemic azoles.[40] Therapy should be continued until at least the neutropenia resolves. For patients whose symptoms have resolved and who are afebrile and clinically stable, therapy should be discontinued, and the patients should be monitored closely for infection recurrence. In high-risk patients, particularly those with persistent fever and neutropenia, the potential presence of clinically occult, diffuse GI or disseminated candidiasis should be considered. The echinocandins and newer azole agents (voriconazole and posaconazole) offer less toxic alternatives or oral agents and are preferred in patients who are intolerant of amphotericin B deoxycholate or who have preexisting renal impairment.[29,47,48] There are limited data on the clinical efficacy of anidulafungin compared with fluconazole, 95% versus 89% cure rates, respectively, in the non-HIV-infected patients.[49]

Antifungal-Refractory Oral Mucosal Candidiasis

Treatment failure is generally defined as persistence of signs and symptoms of OPC or esophageal candidiasis after an appropriate trial of antifungal therapy.[28] Treatment of refractory oral mucosal candidiasis is frequently unsatisfactory, and clinical response is usually short-lived, with rapid and periodic recurrences. The key risk factors for occurrence of refractory candidiasis are advanced stage of AIDS with low CD4 cell counts (<50 cells/mm^3) and repeated or prolonged courses of various systemic antifungal agents, in particular systemic azoles.[29,33,37] Frequent or prolonged use of fluconazole can be associated with fluconazole-refractory candidiasis because of selection of more resistant non–*C. albicans* species. An important initial management strategy is to assess and optimize the antiretroviral therapy of the patient with refractory OPC to help improve the immune function. With the widespread use of HAART, fluconazole-refractory OPC is now less commonly encountered. It is also important to identify and rectify potentially correctable causes of clinical failures of mucosal candidiasis, such as poor drug adherence, adequate dosing, reduced drug absorption associated with hypochlorhydria, and drug–drug interactions.

There have been few controlled studies that assess the effectiveness of antifungals. Doubling of the fluconazole dosage to 400 or 800 mg/day can be effective in some patients with infection caused by *Candida* species of intermediate resistance, although the response may be only transient.[29] Fluconazole oral suspension can be beneficial in some patients because of increased salivary concentrations obtained when the suspension is taken with the swish-and-swallow technique.[37] Patients with fluconazole-refractory mucosal candidiasis can be treated with itraconazole oral suspension because it can be effective in 64% to 80% of patients; however, the benefit is short-lived if chronic suppressive therapy is not maintained.[28,37] Posaconazole suspension has been reported to be successful in ~74% of patients with refractory oral or esophageal candidiasis; voriconazole may also be efficacious in these patients. Amphotericin B oral suspension is another alternative for azole-refractory patients.[32,37] It has broad-spectrum activity against many fungal species and low likelihood of *Candida* species resistance. There are limited data and experience on its use in immunosuppressed patients, and results from small studies have yielded mixed results.[50] Amphotericin B suspension is no longer available commercially in the United States, but it can be prepared extemporaneously by the pharmacy.[50]

Until recently, IV amphotericin B deoxycholate has been the alternative for patients with endoscopically proven disease who have failed fluconazole or itraconazole therapy.[29] Patients with severe disease unresponsive to other agents require IV amphotericin B 0.3 to 0.7 mg/kg/day for 7 to 10 days to achieve clinical response; higher dose or longer treatment duration can be needed in more severe disease.[29,32,33,37] After response, suppressive therapy with amphotericin B is required to increase disease-free intervals. Patients who fail to respond to amphotericin B and require >1 mg/kg/day might be candidates for liposomal amphotericin B preparations because of renal and/or bone marrow toxicities, although at a markedly higher cost. Flucytosine usually is not used as monotherapy because of rapid development of resistance but can be used in combination with an azole or amphotericin B.[29] Less toxic agents that are also effective are voriconazole and the echinocandins.[47–49] Voriconazole, a triazole antifungal available in both oral and IV preparations, appears to be as effective as fluconazole for esophageal candidiasis, and it has shown success in treatment of fluconazole-refractory disease.[46] However, voriconazole has more side effects and multiple pharmacokinetic drug interactions compared to fluconazole.[29,48] Caspofungin is the first of the echinocandins to be approved for esophageal candidiasis; more recently, micafungin and anidulafungin have been approved for this indication. All three echinocandins have similar efficacy and tolerability profile as fluconazole, although higher relapse has been reported with caspofungin and anidulafungin compared with fluconazole.[33,49] Because the echinocandins require IV administration and are expensive, they are primarily used in patients who are refractory to the triazoles or have serious triazole-related adverse effects. As a class, the echinocandins have a favorable adverse effect profile. They are less toxic than amphotericin B (see **Table 129–6**) and have less impact on the cytochrome P450 enzymes than either itraconazole or voriconazole. Immunmodulation with adjunctive granulocyte-macrophage colony-stimulating factor and interferon have been used for refractory oral candidiasis in very limited numbers of patients.[37]

Antifungal Prophylaxis

7 Ensuring that the HIV-infected patient is receiving appropriate antiretroviral therapy to enhance the immune system is perhaps the most important measure in preventing future episodes of mucosal candidiasis (oropharyngeal, esophageal, and vulvovaginal).[33,37] Initial success of treatment often is followed by symptomatic recurrences, especially in patients with advanced or poorly controlled HIV disease. Long-term suppressive therapy with fluconazole is effective in preventing recurrences or new infections of OPC in AIDS and in patients with cancer.[33,37] However, the indications for antifungal prophylaxis and the best long-term management strategy still have not been well established. Fluconazole does not provide complete protection, and breakthrough infections can occur.[29] The reduced risk of recurrence of OPC also has not been demonstrated to improve

survival. In addition, chronic exposure to azole therapy is a concern in that it might lead to the development of refractory disease or emergence of azole resistance.[33,37] However, in a randomized trial of continuous versus episodic fluconazole therapy, continuous therapy did not result in a higher rate of refractory OPC or esophageal disease.[49] Currently, HIV specialists do not recommend primary or secondary prophylaxis for OPC.[32] The rationale includes effectiveness of therapy for acute episodes of OPC, low incidence of serious invasive fungal disease, low mortality associated with mucosal candidiasis, potential for drug interactions, potential for emergence of drug resistance, and the prohibitive long-term cost of prophylaxis.

CLINICAL CONTROVERSY

The optimal strategy for the management of recurrent oral mucosal candidiasis is unclear. Specific criteria for use of secondary prophylaxis are not well defined, and a wide range of approaches can be seen in clinical practice.

8 The decision to use secondary prophylaxis should be individualized for each patient. Secondary prophylaxis can be considered in patients with multiple recurrent episodes of symptomatic OPC or when the disease is sufficiently severe and affecting the quality of life.[32] Patients with a history of one or more episodes of documented esophageal candidiasis and a CD4 T-cell count still <200 cells/mm^3 despite being on HAART are candidates for secondary prophylaxis. Fluconazole 100 mg daily is the usual regimen recommended for OPC and esophageal candidiasis,[32,33,37] although 200 mg three times weekly also appears to be effective.[51] Once-weekly fluconazole (200 mg) is also effective for preventing OPC recurrences in those with less advanced AIDS.[29] Itraconazole solution 200 mg daily is an alternative as suppressive therapy for OPC.[37]

Patients with malignant neoplastic diseases who are receiving irradiation, cytotoxic, and/or immunosuppressive therapy are at high risk for fungal infections in addition to bacterial and viral infections. Prophylaxis of *Candida* infection is controversial, and the results of studies have been conflicting and difficult to evaluate. In the hematopoietic stem cell transplant (HSCT) population, fluconazole prophylaxis is recommended prior to engraftment. Cross-resistance to other azoles may occur among *Candida* species; this should be a treatment consideration in a patient who develops a breakthrough fungal infection. Micafungin is an alternative to fluconazole prophylaxis of candidiasis.[52] The value of antifungal prophylaxis in these patients needs to be considered in the broader context of not only reducing colonization and the risk of superficial candidiasis but also, more importantly, reducing the risk for invasive candidiasis and improving survival. Management of these infections in this patient population is discussed further in Chapter 131.

CLINICAL CONTROVERSY

Several new antifungal agents, in both the triazole and echinocandin class, are now available for the treatment of oral mucosal candidiasis. Although they have demonstrated efficacy, their place in therapy remains to be defined. It is not established which specific agent should be used next after failing fluconazole or itraconazole, and current guidelines now suggest an echinocandin or amphotericin. Factors to consider in the selection can include the underlying clinical condition, the risk for drug, and side effect profiles.

TABLE 129-7 Patient Counseling Tips for Managing Oropharyngeal Candidiasis

1. Clean the oral cavity prior to administering the topical antifungal agent. Daily fluoride rinses can help reduce the risk of caries when using an agent containing sucrose or dextrose.
2. Use the topical antifungal agent after meals, as saliva flow and mouth movements can reduce the contact time.
3. Troches should be slowly dissolved in the mouth, not chewed or swallowed whole, over 15 to 30 minutes, and the saliva swallowed.
4. Suspension should be swished around the mouth in the oral cavity to cover all areas for as long as possible, ideally at least 1 minute, then gargled and swallowed.
5. Remove dentures while medication is being applied to the oral tissues.
6. Use a suspension instead of a troche if xerostomia is present; if a troche is preferred, the patient should rinse or drink water prior to dosing. For xerostomia, suggest nonpharmacologic measures for symptomatic relief (e.g., ice chips, sugarless gum or hard candy, citrus beverages).
7. Dentures should be removed and disinfected overnight using an antiseptic solution (e.g., chlorhexidine 0.12–0.2%). Disinfect oral tissues in addition to dental prosthesis.
8. Complete treatment course even though symptomatic improvement can occur in 48–72 hours.
9. Maintain good oral hygiene. Brush teeth daily (twice daily) and floss, rinse mouth, or brush teeth after eating sweets.
10. Stop smoking; avoid alcohol.

From Akpan A, Morgan R. Oral candidiasis. Postgrad Med J 2002;78:455–459.

EVALUATION OF THERAPEUTIC OUTCOMES

Efficacy end points for oropharyngeal and esophageal candidiasis include rapid relief of symptoms and prevention of complications without early relapse after completion of the course of therapy.[32,37] Sterilization of the oral cavity is not a feasible end point because mycologic eradication is rarely achievable, especially in HIV-positive patients. Symptomatic relief of presenting signs and symptoms (see Table 129–5) generally occurs within 48 to 72 hours of starting therapy, with complete resolution by 7 to 10 days. Patients should be advised about the time course and told to return for reassessment when signs and symptoms recur. It is usually unnecessary for the patient to be reassessed soon after finishing the treatment course. However, HIV patients should be questioned and examined for the occurrence of mucosal candidiasis as part of their regular follow-up. The frequency of monitoring can be more often in neutropenic patients because of concern for dissemination of candidiasis. During the period of neutropenia, temperature should be monitored daily, as well as signs of dissemination.

Efficacy of the antifungal agent is partly influenced by patient adherence to the medication regimen. Patients must be counseled on proper administration and dosing, in particular for topical agents (Table 129–7).[36] Safety end points include monitoring for occurrence of the relevant drug side effects and drug interactions (Table 129–6). Mild GI intolerance can occur with topical therapy, but serious adverse effects are rare. It is still prudent to monitor for hypersensitivity reactions, especially rash and pruritus, that might occur with any medication. GI intolerance is more associated with the oral azoles. Hepatotoxicity can occur when azole therapy is prolonged beyond 7 to 10 days or high doses are used. Periodic monitoring of liver enzymes (alanine transaminase and aspartate amino-transferase) should be considered, especially if prolonged therapy (longer than 21 days) is anticipated. Patients who are receiving IV amphotericin B require daily monitoring by the pharmacist.

MYCOTIC INFECTIONS OF THE SKIN, HAIR, AND NAILS

Superficial mycotic infections of the skin are referred to as *dermatophytoses.* They are common infections that usually are caused by dermatophytes classified by genera: *Trichophyton, Epidermophyton,* and *Microsporum.*[53] Dermatophytes have the ability to penetrate keratinous structures of the body. These infections affect both male and female genders and all races. Reservoirs of mycotic infections include humans, animals, and soil.[53] Individuals can develop an infection if they come in contact with a reservoir in addition to having a conducive environment for mycotic growth (i.e., moist conditions).[54] Risk factors for the development of an infection include prolonged exposure to sweaty clothes, failure to bathe regularly, many skinfolds, sedentariness, and confinement to bed.[54]

Mycotic infections of the skin have a classic appearance that consists of a central clearing surrounded by an advancing red, scaly, elevated border.[54] Infections of the nail can appear chalky and dull yellow or white and become brittle and crumbly.

Diagnosis usually is based on patient history, as well as the physical examination.[55] Diagnostic tests include direct microscopic examination of a specimen after the addition of KOH or fungal cultures. The KOH test is quick, inexpensive, and easy to perform, whereas cultures are more expensive and take longer to obtain results. Diagnostic tests are recommended when systemic therapy is likely to be prescribed.[55]

9 A general approach to treatment of superficial mycotic infections includes keeping the infected area dry and clean and limiting exposure to the infected reservoir. Topical agents generally are considered to be first-line therapy for infections of the skin. Oral therapy is preferred when the infection is extensive or severe or when treating tinea capitis or onychomycosis.[56–58] Table 129–8 lists specific treatments for each mycotic infection. Superficial mycotic infections are categorized by the pattern and site of infection.[53] The most commonly occurring infections in North America are detailed in the following sections.

CLINICAL CONTROVERSY

Evidence for the treatment of superficial mycotic infections of the skin and hair comes from a small number of trials with relatively small numbers of subjects.

TINEA PEDIS

Tinea pedis is the most common dermatophytoses (affecting ~70% of adults). It is better known as "athlete's foot" and occurs in hot weather, with exposure to surface reservoirs (locker room floors), and with use of occlusive footwear.[54] Treatment with topical therapy for 2 to 4 weeks often is adequate for mild infections; however,

TABLE 129-8 Treatment of Mycoses of the Skin, Hair, and Nails

	Topical[a,b]	Oral[c]
Tinea pedis	Butenafine, daily	Fluconazole 150 mg 1 per week × 1–4 weeks
Tinea manuum	Ciclopirox, twice daily	Ketoconazole 200 mg daily × 4 weeks
Tinea cruris	Clotrimazole, twice daily	Itraconazole 200–400 mg/day × 1 week
Tinea corporis	Econazole, daily	Terbinafine 250 mg/day × 2 weeks
	Haloprogin, twice daily	
	Ketoconazole cream, daily	
	Miconazole, twice daily	
	Naftifine cream, daily; gel, twice daily	
	Oxiconazole, twice daily	
	Sulconazole, twice daily	
	Terbinafine, twice daily	
	Tolnaftate, twice daily	
	Triacetin cream, solution, 3 times daily	
	Undecylenic acid, various preparations: apply as directed	
Tinea capitis	Shampoo only in conjunction with oral therapy or for treatment of asymptomatic carriers	Terbinafine 250 mg/day × 4–8 weeks
Tinea barbae		Ketoconazole 200 mg daily × 4 weeks
	Ketoconazole 2 per week × 4 weeks	Itraconazole 100–200 mg/day × 4–6 weeks
	Selenium sulfide daily × 2 weeks	Griseofulvin 500 mg/day × 4–6 weeks
Pityriasis versicolor	Clotrimazole, twice daily	Ketoconazole
	Econazole, daily	
	Haloprogin, twice daily	Fluconazole
	Ketoconazole, daily	
	Miconazole, twice daily	Itraconazole 200 mg daily × 3–7 days
	Oxiconazole cream only, twice daily	
	Sulconazole, twice daily	
	Tolnaftate, three times daily	
Onychomycosis	Ciclopirox 8% nail lacquer: apply solution at night for up to 48 weeks	Terbinafine 250 mg/day × 6 weeks (finger), 12 weeks (toe)
Fingernail		Itraconazole 200 mg twice daily × 1 week per month; repeat for total of two pulses (finger) or three pulses (toe)
Toenail		Itraconazole 200 mg daily for 6 weeks (finger) or 12 weeks (toe)
		Fluconazole 50 mg daily or 300 mg once weekly for ≥6 months (finger) or 12 months (toe)

[a]Other products are available, including combination products.
[b]Length of therapy depends on mycotic sensitivity and severity of infection.
[c]Only capsule formulation studied; give with food for increased absorption.

severe infections or involvement of the nails requires oral therapy[54] (see Table 129–8). Recurrence of infection occurs in up to 70% of individuals. Prolonged treatment with either topical or systemic therapy may be required.[55,56]

TINEA MANUUM

Tinea manuum usually involves the palmar surface of the hands, is unilateral, and can involve the feet. Treatment of this infection is similar to tinea pedis (see Table 129–8). Emollients that contain lactic acid also can be useful.[54]

TINEA CRURIS

Tinea cruris is an infection of the proximal thighs and buttocks.[57] It is referred to as "jock itch" and is more common in males. The scrotum and penis often are spared from infection. Treatment with topical therapy is recommended and should continue for 1 to 2 weeks after symptom resolution. Severe infections can require oral therapy (see Table 129–8). Relief of pruritus and burning can be facilitated by the use of short-term (2 or 3 days) topical steroids (2.5% hydrocortisone).[54]

TINEA CORPORIS

Tinea corporis is an infection of the glabrous skin of the trunk and extremities.[57] Therapy is similar to that for tinea pedis, tinea manuum, and tinea cruris (see Table 129–8).

TINEA CAPITIS

Tinea capitis is a mycotic infection involving the scalp, hair follicles, and adjacent skin[58,59] that primarily affects children. Treatment should consist of oral therapy, as well as the cleaning of combs and brushes, which can be contaminated (see Table 129–8). Daily shampooing is recommended for removal of scales. Some children and adults can be asymptomatic carriers, thereby facilitating spread of the infection.[58] Family members who culture positive for Trichophyton tonsurans should be treated with an antifungal shampoo (e.g., ketoconazole, selenium sulfide, or povidone-iodine).[58]

TINEA BARBAE

Tinea barbae affects the hairs and follicles of beards and mustaches.[58] Treatment is similar to that for tinea capitis (see Table 129–8). Removal of the beard or mustache is recommended.[54]

PITYRIASIS VERSICOLOR

Hyper- and hypopigmented scaly patches characterize pityriasis versicolor which is also known as Dermatomycosis furfuracea and is caused by *Malassezia globosa* and *M. fur*. These patches are found on the trunk and extremities.[60] It is more common in adults and in areas with tropical ambient temperatures. Topical treatment usually is adequate unless there is extensive involvement, recurrent infections, or failure of topical therapy.[60] A study of 100 subjects treated with either ketoconazole 2% shampoo or selenium sulfide 2.5% shampoo showed that ketoconazole was significantly more effective that selenium sulfide (89% vs. 35% cure rate).[61]

ONYCHOMYCOSIS (TINEA UNGUIUM)

Onychomycosis is a fungal infection of the nail apparatus and is the most common single cause of nail dystrophy, affecting up to 8% of the general population and accounting for up to 50% of all nail problems.[62–64] Onychomycosis more commonly affects the toenails (2% to 14% of adults), ~4 to 19 times more frequently than fingernails, with prevalence increasing with age.[64] This can be because of the slower growth of toenails (three times slower than fingernails), making it easier for fungi to establish infection. Onychomycosis has a significant impact on quality of life, both functional and psychosocial. In addition, the affected nails can disrupt the integrity of the surrounding skin, potentially increasing the risk of secondary bacterial infections.[64]

Dermatophytes are the most frequent causes of onychomycois (~90% in toenail and ~50% in fingernail infections).[65] The dermatophytes responsible for causing >90% of cases of onychomycosis are *Trichophyton rubrum* (71%) and *Trichophyton mentagrophytes* (20%).[58,59] Less common fungi causing onychomycosis are the nondermatophytic molds (2.3% to 11%) and yeasts (5.6%). *C. albicans* is the most commonly isolated yeast and typically affects fingernails rather than toenails.[62,66] Risk factors for dermatophytic onychomycosis are increasing age (especially older than 40 years), family history and genetic factors, immunodeficiency (e.g., HIV, renal transplant, immunosuppressive therapy, and defective polymorphonuclear chemotaxis), diabetes mellitus, psoriasis, peripheral vascular disease, smoking, prevalence of tinea pedis, frequent nail trauma, and sporting activities such as swimming.[66,67] These risk factors also appear to apply to recurrence of onychomycosis. Mold onychomycosis does not seem to be associated with systemic or local predisposing factors, but there is a risk of systemic dissemination in immunosuppressed patients.[66] *Candida* onychomycosis seems to always occur in immunosuppressed patients.[66]

Onychomycosis can present in four or five different major clinical forms, of which lateral distal subungual onychomycosis (DSO) is the most common type.[62,66,68] In DSO, the nail plate, the nail bed, and, in advanced cases, the matrix are all affected, and *T. rubrum* is the most common etiologic cause. The worst case of onychomycosis is progression of the infection to total dystrophic onychomycosis, characterized by almost complete destruction of the nail plate. White superficial onychomycosis (WSO) is usually caused by *T. mentagrophytes,* where the infection is localized to the surface of the nail plate. In proximal subungual onychomycosis (PSO), the fungi (usually *T. rubrum*) invade the nail through the proximal nail fold and spread to the nail plate and matrix. Although PSO is relatively uncommon in the general population, it occurs most frequently in severely immunocompromised patients and is often considered a marker for AIDS.[66,68] Because of the multifactorial etiology of onychomycosis, it is important to differentiate onychomycosis from other causes of nail dystrophies so that the patient receives appropriate therapy and is not subjected to prolonged treatment with unnecessary drugs. Besides clinical history and physical examination, proper diagnosis of onychomycosis can include the combination of direct microscopy of scrapings from the appropriate nail area to look for fungal hyphae and fungal cultures, and, if necessary, histologic examination.[63,69,70] Table 129–9 provides a differential diagnosis for fungal nail diseases.[71]

TABLE 129-9 Differntial Diagnosis of Fungal Nail Infections

Diagnosis	Features Consistent with Diagnosis
Psoriasis	Nail pitting, rash elsewhere on body, family history of psoriasis
Lichen planus	Nail atrophy, scarring at proximal aspect of the nail
Periungual squamous cell carcinoma	Single nail affected, pain, warty nail fold change, or ooze from the edge of nail
Yellow nail syndrome	Multiple nails turn yellow, grow slowly, increased longitudinal and transverse curvature, intermittent pain and shedding, associated with chronic sinusitis, bronchiectasis, lymphadema
Trauma	Single nail affected, homogeneous alteration of nail color and altered shape of nail

TREATMENT

GENERAL APPROACH

Onychomycosis merits proper assessment and treatment consideration because it is a debilitating disease and can exert a negative impact on quality of life (e.g., cosmetic and psychosocial effects, pain, discomfort, and decreased ambulation).[63,66,72] It is reasonable to not treat persons with minimal toenail involvement and no associated symptoms.[71] Although definitive data are lacking regarding the risk of progression of untreated disease, it can lead to complications such as cellulitis or reduced mobility, which can further compromise peripheral circulation in those with diabetes or peripheral vascular disease; additionally, infected nails can serve as a source of transmission of fungi to other areas of the body, as well as to other people, such as close household contacts, or in communal bathing places.[63,66,72,73] Treatment decisions should be made on an individual basis. The primary end point of treatment is eradication of the organism, with secondary end points being clinical cure and improvement.[63]Assessment of clinical success (cure or improvement) requires followup for several months after the end of treatment because of the slow growth rate of nails, especially toenails (1 mm/month).[63,66] Successful eradication of the fungus does not always result in normalization of the nails because they can have been dystrophic prior to infection. This can cause patient dissatisfaction, especially if this is not explained before starting treatment.[68] There are several factors that must be taken into account on a patient-by-patient basis to ensure appropriate treatment decisions (Table 129–10). The impact of patient adherence on the success of treatment cannot be overemphasized. Patients need to be educated about their disease, expectations of treatment, and prevention of recurrence, and various strategies have been suggested to improve treatment success.[70]

In general, onychomycosis of the toenail is more difficult to treat than fingernails, requires longer treatment duration, and is associated with a higher recurrence. The treatment options for onychomycosis include oral and topical therapies, mechanical or chemical nail avulsion, or a combination of these. Mechanical or chemical nail avulsion is used primarily as adjunct to oral therapy in patients with total dystrophic onychomycosis, in whom there is severe onycholysis and extensive nail thickening or longitudinal spikes. This is to enhance penetration of the antifungal agent to the entire nail plate and unit.[63,70,73]

TABLE 129-10 Factors that may Impact Treatment Decisions and Outcomes

- Type and severity of onychomycosis
- Causative organism–dermatophyte versus molds or yeast
- Infection of the finger versus toenail
- Extent of disease–involvement of matrix, one or two lateral edges, number of nails
- Thickness of nail plate
- Other sites of mycotic infection (palms, soles, toe webs)
- Other nail alterations affecting outcome (onycholysis, paronychia, dermatophytoma, etc.)
- Other nail diseases and symptoms
- Age and underlying medical conditions (diabetes, poor perfusion, immunocompromised)
- Drug interactions and adverse effects
- Cost of therapy

Data from Effendy I, Lecha M, Feuilhade de Chauvin M, et al. Epidemiology and clinical classification of onychomycosis. J Eur Acad Dermatol Venereol 2005;19(Supp1 1):8–12; Gupta AK, Tu LQ. Onychomycosis therapies: Strategies to improve efficacy. Dermatol Clin 2006;24:381–386; Lecha M, Effendy I, Feuilhade de Chauvin M, et al. Treatments options–Development of consensus guidelines. J Euro Acad Dermatol Venereol 2005;19(Suppl 1):25–33; and Gupta AK, Tu LQ. Therapies for onychomycosis: a review. Dermatol Clin 2006;24:375–379.

CLINICAL CONTROVERSY

Treatment of onychomycosis is associated with a high failure rate of 20% to 50%. There appears to be a sound pharmacologic rationale behind the use of combination therapy, which has been used to improve overall efficacy. However, the best combination of agents for use in treating onychomycosis is unclear, and there is no consensus on when to use such agents.

TOPICAL THERAPY

⑩ Conventional topical antifungal products are available as creams, ointments, powders, and solutions. Because these formulations do not penetrate through the nail plate to the nail bed, they are most appropriately used when the nail plate has been removed.[73] Even then cure rates are still low and variable and are influenced by patient adherence.[66,73] Nail lacquer represents the latest advance in topical formulation. The volatile vehicle, used to deliver the drug, evaporates and leaves an occlusive film with a high drug concentration on the nail surface.[66,73] There are only two marketed nail lacquers, amorolfine 5% and ciclopirox 8% solution (Penlac), the latter being the only one approved in North America for the treatment of mild to moderate onychomycosis caused by *T. rubrum* without lunula involvement.[66,72,73] Ciclopirox, a hydroxypyridine, has a broad spectrum of antifungal activity (dermatophytes, *Candida* species, and some molds) and requires treatment for 1 year. Although ciclopirox was significantly better than vehicle alone, the mycologic cure rate was only 32% with ciclopirox versus 10% for vehicle alone after 48 weeks of treatment; the overall treatment cure (mycologic cure with 0% to 10% involvement of the target nail) was 9% versus 0.9% for drug and vehicle, respectively.[66,73] However, higher mycologic cure rates of 45% to 65% have been reported in a variety of open-label trials involving 6 to 12 months of treatment.[66] Amorolfine appears to produce higher mycologic and treatment cure rates than ciclopirox.[66,72] Most experts consider topical therapy a feasible option when the infection is superficial involving the nail plate without matrix involvement, such as WSO, involves a partial area of the nail plate not exceeding 50% (owing to difficulty of applying treatment to the margin of the nail), is limited to a few (three or four) nails, is in the very early stages of DSO when infection is still confined to the distal edge of the nail, or when systemic therapy is contraindicated.[63,66,72] Combining topical therapy with debridement of the affected nail (thus diminishing the amount of nail requiring treatment) may increase the likelihood of successful treatment, although there is no strong supporting evidence.[71] Topical therapy is not associated with systemic adverse effects or drug interactions. Any adverse effect will be localized to the application site, such as mild erythema in the adjacent skin area.

SYSTEMIC THERAPY

Oral antifungal therapy is considered to be more effective than topical for treating onychomycosis. Terbinafine and itraconazole (capsule), the current first-line agents for treatment, have yielded higher efficacy rates using shorter treatment periods (generally 3 months or shorter) for toenail and fingernail onychomycosis compared with the traditional agents, such as griseofulvin and ketoconazole, which are rarely used nowadays. Terbinafine, an allylamine, exerts fungicidal activity and demonstrates the greatest in vitro activity against dermatophytes compared with the other oral antifungals; it has good activity against nondermatophyte molds

and only marginal activity against *Candida* species.[63,73] Like other azoles, itraconazole is fungistatic, has a broad antifungal spectrum, and is very active against dermatophytes, nondermatophytes, and *Candida* species.[63,73] Both agents have lipophilic and keratinophilic properties, which explains their excellent penetration (appearing in the nail plate within days of treatment initiation) and accumulation in the nails, achieving concentrations far exceeding the minimal inhibitory concentration (MIC) of most dermatophytes. Nail terbinafine concentrations are detected within 1 week of starting therapy, whereas itraconazole can be detected 1 (fingernails) to 2 weeks (toenails) after starting therapy.[66] Both drugs are slowly eliminated from the nail, with effective drug concentrations persisting in nails for 30 to 36 weeks after completion of treatment with terbinafine and for 27 weeks with itraconazole.[68] The persistence of drug in the nails explains in part the long-term protection against relapses after the end of treatment and also permits use of intermittent (pulse) dosing.

The treatment of toenail onychomycosis requires a 12-week course, whereas a 6-week course is adequate for fingernail onychomycosis with either drug.[63,68] In general, cure rates of 80% to 90% for fingernail infection and 70% to 80% for toenail infection can be expected.[63] Terbinafine is licensed for daily dosing (see Table 129–8).[63,68,74] Various terbinafine pulse regimens have been evaluated;[73] in some trials, pulse dosing was less effective than continuous dosing, and it did not provide clear safety advantages.[69,70] One trial demonstrated similar efficacy of pulse terbinafine compared with continuous therapy and better outcomes compared with pulse itraconazole treatment.[75] Itraconazole pulse therapy is the preferred method over continuous dosing for fingernail infections, and it is licensed as twice-daily dosing for a 1-week cycle per month for 2 consecutive months (i.e., two pulses), or as daily therapy for 6 weeks (see Table 129–8).[68,74] Although itraconazole pulse therapy is not approved by the US Food and Drug Administration (FDA), three or four pulses are effective for toenail infections; otherwise, half the dose is taken daily for 3 months (see Table 129–8).[68,74] In addition to lower drug cost, the potential advantages of itraconazole pulse therapy compared with continuous therapy are a lower risk of adverse drug effects and improved patient adherence.

Terbinafine is generally considered by most experts as the first-line agent for onychomycosis; itraconazole is the alternative. Direct comparative trials generally have shown that terbinafine is more effective than itraconazole either by continuous or pulse dosing.[63,72,73] Mycologic cure rates for terbinafine range from 77% to 100% depending on the study.[66] In a cumulative meta-analysis of randomized, controlled trials, mycologic cure rates for terbinafine, itraconazole pulse, itraconazole continuous, fluconazole, and griseofulvin were 76% ± 3%, 63% ± 7%, 59% ± 5%, 60% ± 6%, and 48% ± 5%, respectively.[78] An earlier meta-analysis and systematic review also reported that continuous terbinafine was the most effective therapy for toenail onychomycosis.[72,73] In addition, terbinafine was reported to achieve high cure rates in high-risk immunosuppressed patients, such as diabetics and organ transplant recipients, comparable to the immunocompetent population, with no significant adverse effects or drug interactions. It also appears to be effective in HIV patients and nondermatophyte infections.[74,81] A pharmacoeconomic analysis of oral and topical (ciclopirox) therapies showed that from a managed care perspective, terbinafine was the most cost-effective therapy in terms of highest success rate, lowest relapse rate, and highest number of disease-free days for both fingernail and toenail infections.[82] An analysis that looked only at oral therapy estimated that the cost per cure with the use of terbinafine (based on cure rates from clinical trials) ranged from $2,439 to $7,944, depending on disease severity.[83] Compared with the amount of money a patient would consider reasonable to spend on treatment, the current charges for a course of systemic therapy are considerably higher.[83,84]

CLINICAL CONTROVERSY

There is controversy regarding the cost–benefit ratio of treating onychomycosis. People commonly receive treatment without a proper diagnosis of onchymycosis. These patients are not accounted for in any pharmacoeconomic analysis as such this inappropriate treatment will markedly increase the cast per cure. Also relevant to decision making are the risks of treatment and the effects of treatment on quality of life. A study translating these considerations into an amount of money a patient would consider reasonable to spend on treatment found the current costs of a course of therapy are much greater than this sum.[84]

Both terbinafine and itraconazole generally are well tolerated. The more common adverse effects reported with terbinafine are GI (e.g., diarrhea, dyspepsia, nausea, and abdominal pain), dermatologic (e.g., rash, urticaria, and pruritus), and headache; less common adverse effects are taste disturbances, fatigue, inability to concentrate, and asymptomatic liver enzyme abnormalities.[68,72,74] Terbinafine can cause transient decrease in absolute lymphocyte counts; hence, monitoring of complete blood counts can be useful, especially in immunocompromised patients.[74] Although uncommon, severe adverse effects have been reported with terbinafine, including erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, pancytopenia, lupus erythematosus, psoriasis, hair loss, and hepatotoxicity. Although the incidence of severe hepatotoxicity is considered rare, the FDA issued a public health advisory in 2001 regarding the association of terbinafine tablets with 16 possible cases of liver failure, including 2 liver transplants and 11 deaths.[85] Terbinafine thus is not recommended for patients with chronic or active liver disease, although hepatotoxicity can occur in patients with no preexisting liver disease or serious underlying medical condition. Prior to initiating terbinafine treatment, it is recommended to obtain appropriate nail specimens for laboratory testing to confirm the diagnosis of onychomycosis. Liver function parameters (serum transaminases) should be assessed at baseline and periodically during treatment with terbinafine.[74,85]

The common adverse effects of itraconazole are similar to those of terbinafine, such as GI disturbance, dermatologic disorders, and headache; less common adverse effects include dizziness, fatigue, fever, decreased libido, and asymptomatic liver enzyme abnormalities (1% to 5% with continuous dosing and ~2% with pulse dosing).[68,72,86] Although still considered rare, 24 serious cases of liver failure, including transplantation and death, have been reported with the use of itraconazole, resulting in an FDA public health advisory warning.[85] Some of these patients did not have preexisting liver disease or serious underlying medical conditions, and some developed within the first week of treatment. Itraconazole should be avoided in patients with elevated liver enzymes or active liver disease or in those who have experienced other drug-induced liver toxicity. Liver function parameters (serum transaminases) should be assessed prior to and periodically during treatment. However, some experts have suggested that frequent monitoring is not as necessary if pulse therapy is used because symptomatic hepatotoxicity has not been reported with pulse therapy.[86] In addition, there is an FDA warning on the risk of developing congestive heart failure (CHF) associated with the use of itraconazole, possibly related to its potential negative inotropic effect.[63,76] Therefore, itraconazole should not be used in patients with evidence of ventricular dysfunction, such as CHF. Symptomatic assessment for the development of CHF also should

be included as part of therapy monitoring. Before a patient is subjected to several months of itraconazole treatment, it is important to confirm the diagnosis of onychomycosis.

In contrast to the azoles, terbinafine does not inhibit the cytochrome P450 (CYP) 3A4 isoenzymes, but it is a potent inhibitor of the CYP2D6 isoenzymes, which are responsible for metabolism of tricyclic antidepressants and other psychotropic drugs.[63,68,74] The most significant drug interactions with terbinafine are decreased clearance of 33% by cimetidine and increased clearance of 100% by rifampin. Other drug interactions of variable clinical significance are tricyclic antidepressants, cyclosporine, caffeine, theophylline, and terfenadine. Itraconazole and its major metabolite can inhibit the CYP3A4 isoenzymes and result in numerous clinically significant drug interactions where coadministration with several drugs are contraindicated (e.g., alprazolam, midazolam, triazolam, pimozide, lovastatin, simvastatin, cisapride, and terfenadine).[63,68,74]

Fluconazole is also active against dermatophytes, *Candida* species, and some nondermatophytes;[68,72] however, it does not have current FDA-approved indication for treatment of onychomycosis. The overall mycologic cure rate of fluconazole is 48%, which is lowest compared with all other oral agents.[78] The most effective dose and treatment duration have not been clearly established, with a variety of dosing regimens used, ranging from 50 mg daily to 300 mg once weekly for 6 to 12 months (see Table 129–8).[68,74] The advantages of fluconazole include a relatively good safety profile and fewer drug interactions compared with itraconazole.[68,74]

These three oral antifungal agents have superseded the use of griseofulvin and ketoconazole as treatments of choice for onychomycosis.[63,72,73] Griseofulvin has a narrow antifungal spectrum, low clinical efficacy, especially for toenail infections, high relapse rates, and the need for prolonged treatment duration (up to 12 to 18 months for toenails). Use of ketoconazole is also associated with high relapse rates, and the prolonged treatment duration carries an increased risk of hepatotoxicity.

TREATMENT RESPONSE AND RECURRENCE

Treatment failures and recurrence rates of infection following initial cure are high, ranging from 20% to 50%.[63,71] Recurrence could be either a relapse (original infection not completely cured) or reinfection (new infection after achieving a cure of the original). Factors associated with poor response to systemic therapy include a compromised immune system (AIDS), reduced blood flow (diabetes, peripheral vascular disease, vasculitis, connective tissue disease, and CHF), coexisting nail disease (psoriasis), nail factors (slow growth, thick nails, and severe disease), drug-resistant organisms because of extensive prior drug exposure, and reduced bioavailability (absorption problems, poor compliance, and drug interactions).[68,71] To improve treatment outcomes and reduce recurrence, patients should be counseled on the importance of proper foot hygiene, for example, wearing breathable footwear and 100% cotton socks with frequent changes, keeping the nails short and clean, keeping the feet dry, protecting the feet in shared bathing areas, treating tinea pedis, and controlling other predisposing medical conditions.[71]

The use of combination therapy (topical–oral or oral–oral agents) can improve cure rates and shorten treatment duration, as this approach provides complementary mechanisms of attack.[71,72] Studies in Europe have reported favorable results achieved with itraconazole or terbinafine combined with amorolfine.[71,72] To date no specific combination has been approved or endorsed for use. Other novel approaches include giving supplemental therapy and use of boosted therapy.[71,72] The efficacy and role of either approach remain to be defined.

CHAPTER 130

Invasive Fungal Infections

PEGGY L. CARVER

KEY CONCEPTS

1. Systemic mycoses can be caused by pathogenic fungi and include histoplasmosis, coccidioidomycosis, cryptococcosis, blastomycosis, paracoccidioidomycosis, and sporotrichosis, or infections by opportunistic fungi such as *Candida albicans, Aspergillus* species, *Trichosporon, Candida glabrata, Fusarium, Alternaria*, and *Mucor*.
2. The diagnosis of fungal infection generally is accomplished by careful evaluation of clinical symptoms, results of serologic tests, and histopathologic examination and culture of clinical specimens.
3. Histoplasmosis is caused by *Histoplasma capsulatum* and is endemic in parts of the central United States along the Ohio and Mississippi River valleys. Although most patients experience asymptomatic infection, some can experience chronic, disseminated disease.
4. Asymptomatic patients with histoplasmosis are not treated, although patients who do not have acquired immune deficiency syndrome (AIDS) patients with evident disease are treated with either oral ketoconazole or intravenous amphotericin B; AIDS patients are treated with amphotericin B and then receive lifelong suppression.
5. Blastomycosis is caused by *Blastomyces dermatitidis* and generally is an asymptomatic, self-limited disease; however, reactivation can lead to chronic disease. Although treatment for self-limited disease is controversial, patients with chronic pulmonary disease or extrapulmonary disease should be treated with ketoconazole, and those with central nervous system (CNS), progressive, or life-threatening disease should receive amphotericin B.
6. Coccidioidomycosis is caused by *Coccidioides immitis* and is endemic in some parts of the southwestern United States. It can cause nonspecific symptoms, acute pneumonia, or chronic pulmonary or disseminated disease. Primary pulmonary disease (unless severe) frequently is not treated, whereas extrapulmonary disease is treated with amphotericin B, and meningitis is treated with fluconazole.
7. Cryptococcosis is caused by *Cryptococcus neoformans* and occurs primarily in immunocompromised patients. Patients with acute meningitis are treated with amphotericin B with flucytosine. Patients infected with human immunodeficiency virus (HIV) often require long-term suppressive therapy with fluconazole or itraconazole.
8. A variety of *Candida* species (including *C. albicans, C. glabrata, Candida tropicalis, Candida parapsilosis, and Candida krusei*) can cause diseases such as mucocutaneous, oral, esophageal, vaginal, and hematogenous candidiasis, as well as candiduria. Candidemia can be treated with a variety of antifungal agents; the optimal choice depends on previous patient exposure to antifungal agents, potential drug interactions and toxicities of each agent, and local epidemiology of intensive care unit or hematology-oncology centers.
9. Aspergillosis can be caused by a variety of *Aspergillus* species that can cause superficial infections, pneumonia, allergic bronchopulmonary aspergillosis, or invasive infection. Treatment with amphotericin B or voriconazole generally is instituted but often is not successful. Combination therapy, while widely used, lacks clinical trial data to support its use.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

For many years, fungal infections were classified as either superficial "nuisance diseases," such as athlete's foot or vulvovaginal candidiasis, or as relatively rare infections confined primarily to endemic areas of the country. When invasive fungal infections were encountered, amphotericin B was the only consistently effective, systemically active agent available for the treatment of systemic mycoses. 1 Advances in medical technology, including organ and bone marrow transplantation, cytotoxic chemotherapy, the widespread use of indwelling intravenous (IV) catheters, and the increased use of potent broad-spectrum antimicrobial agents all have contributed to the dramatic increase in the incidence of fungal infections worldwide.

Fungal infections have emerged as a major cause of death among cancer patients and transplant recipients.[1–4] In addition, patients with AIDS experience substantially more frequent and severe forms of cryptococcosis, histoplasmosis, coccidioidomycosis, and mucocutaneous (esophageal, oral, and vulvovaginal) candidiasis.

Problems remain in the diagnosis, prevention, and treatment of fungal infections. Unlike the available diagnostic techniques for most bacterial pathogens, there remains a host of unresolved issues regarding standardization of susceptibility testing methods, in vitro and in vivo models of infection, the usefulness of monitoring antifungal plasma concentrations, and the development and identification of resistant pathogens.[1,5,6] The Infectious Diseases Society of America published guidelines for the treatment of many commonly encountered fungal infections. These guidelines provide summaries of the literature and a consensus of expert opinions regarding the treatment of these difficult infections.[6]

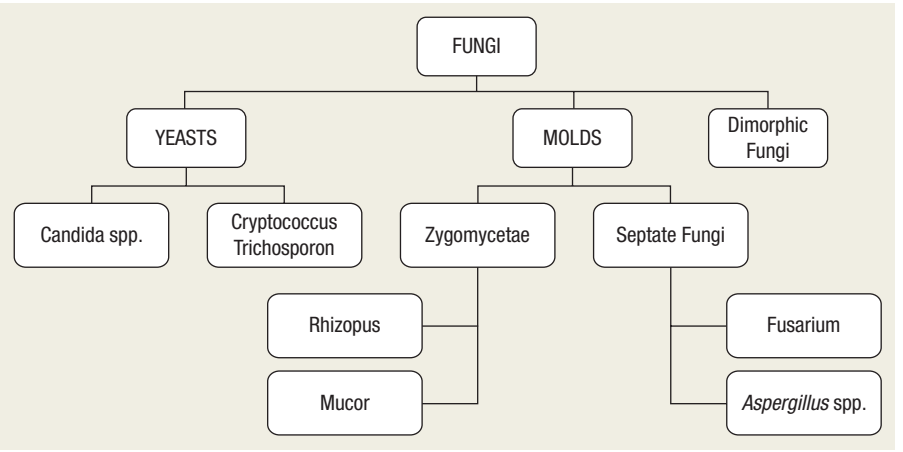

FIGURE 130-1. Morphologically, pathogenic fungi can be grouped as either filamentous molds or unicellular yeasts. *Molds* grow as multicellular branching, thread-like filaments (hyphae) that are either septate (divided by transverse walls) or coenocytic (multinucleate without cross walls).

MYCOLOGY

Fungi are eukaryotic organisms with a defined nucleus enclosed by a nuclear membrane; a cytoplasmic membrane containing lipids, glycoproteins, and sterols, mitochondria, Golgi apparatus, and ribosomes bound to endoplasmic reticulum; and a cytoskeleton with microtubules, microfilaments, and intermediate filaments. Fungi have rigid cell walls composed of chitin, cellulose, or both that stain with Gomori methenamine silver or periodic acid–Schiff reagent. Most fungi, except *Candida* species, are too weakly gram-positive to be seen well on Gram stain. *Cryptococcus neoformans* has a polysaccharide capsule surrounding the cell wall.[6]

Morphologically, pathogenic fungi can be grouped as either filamentous molds or unicellular yeasts (Fig. 130–1). *Molds* grow as multicellular branching, threadlike filaments (hyphae) that are either septate (divided by transverse walls) or coenocytic (multinucleate without cross walls). On agar media, molds grow outward from the point of inoculation by extension of the tips of filaments and then branch repeatedly, interweaving to form fuzzy, matted growths called *mycelia*. Yeasts are oval or spherically shaped unicellular forms that generally produce pasty or mucoid colonies on agar medium similar to those observed with bacterial cultures. Yeasts have rigid cell walls and reproduce by budding, a process in which daughter cells arise from pinching off a portion of the parent cell.

Fungi reproduce by forming spores asexually through mitosis to produce motile sporangiospores or nonmotile conidia (singular, conidium), or they reproduce sexually through meiosis to produce ascospores, basidiospores, oospores, or zygospores. Although terms such as *spore* and *conidia* should no longer be used interchangeably, some newer literature and much of the older medical literature continue to confuse these terms.

Many pathogenic fungi, termed *dimorphic fungi*, exist as either a yeast or a mold, depending on pathogen, site of growth (in the host or in the laboratory setting), and temperature. Usually yeasts are the parasitic form that invades human or animal host tissue, whereas molds are the free-living form found in the environment. For example, *Histoplasma capsulatum* exists as a yeast in humans and as a mold in the laboratory.[1]

SUSCEPTIBILITY TESTING OF ANTIFUNGAL AGENTS

Most laboratories do not routinely perform susceptibility tests on fungal isolates, but standardized methods for performing these tests are being developed and are now available for testing selected yeasts. To date, reference broth macrodilution and microdilution methods have been established for *Candida* and *Cryptococcus* species, whereas the broth microdilution method has been standardized for filamentous fungi. Additionally, minimal inhibitory concentration (MIC) reference ranges for American Type Culture Collection (ATCC) quality control strains have been established against various antifungal agents, as well as interpretive breakpoints for fluconazole, itraconazole, and flucytosine against *Candida* species[5] (Tables 130–1 and 130–2). For further detail, refer to the section outlining treatment of *Candida* infections. Reliable and convincing interpretive breakpoints are not yet available for amphotericin B. The National Committee for Clinical Laboratory Standards' (NCCLS) M27-A methodology does not reliably identify amphotericin B–resistant isolates; variations of the methodology using different media appear to enhance detection of resistant isolates.[5,7] The breakpoints should be used following testing with the standardized, reproducible laboratory methodology (NCCLS 27-A) used to develop the test and they should be interpreted in the context of the delivered dose of the antifungal agent.

Because in vitro correlations with in vivo outcomes in patients are not yet known, the role of routine susceptibility testing is unknown at this time. Several concerns need to be considered as the use of MIC breakpoints is incorporated into the clinical practice setting. First, MICs are not actual physical measurements; rather, they provide estimates of drug activity. Because the MICs obtained can span greater than three twofold dilutions for the same isolate despite meticulous technique, MICs must be interpreted with caution. Second, host factors contribute greatly to clinical outcome. The same isolate in an immunocompetent patient might not result in the same outcome as in an immunocompromised patient. Thus, in vitro susceptibility does *not* necessarily equate with in vivo clinical success, and in vitro resistance might *not* always correlate with treatment failure. Susceptibility testing occasionally is indicated, for example, in a patient with prolonged fungemia with a presumed susceptible isolate. Because of wide interlaboratory variability in test results, isolates should be tested at specialty laboratories that routinely perform these specialized tests. Susceptibility testing is most helpful in dealing with infections caused by non-*albicans* species of *Candida*.[5,7]

RESISTANCE TO ANTIFUNGAL AGENTS

It is important to distinguish between clinical resistance and microbial resistance. *Clinical resistance* refers to failure of an antifungal agent in the treatment of a fungal infection that arises from factors other than microbial resistance, such as failure of the antifungal agent to reach the site of infection or inability of a patient's immune system to eradicate a fungus whose growth is retarded by an antifungal agent.[8]

TABLE 130-1 General Patterns of Susceptibility and Interpretive Breakpoints of *Candida* Species[a]

	Patterns of Susceptibility							
	Azoles				*Echinocandins*			*Amphotericin*
***Candida* Species**	**Fluconazole**	**Itraconazole**	**Voriconazole**	**Posaconazole**	**Caspofungin**	**Micafungin**	**Anidulafungin**	**Amphotericin B**
C. albicans	+++ S	+++ S	+++ S	S	+++	+++	+++	+++
C. tropicalis	+++ S	+++ S	+++ S	+++ S	+++ S	+++ S	+++ S	+++ S
C. parapsilosis	S	S	S	S	S[d]	S[d]	S[d]	S
C. glabrata	++ S-DD to R[b]	++ S-DD to R[c]	++	S	S	S	S	S-I[e]
C. krusei	R	S-DD to R[c]	S	S	S	S	S	S-I[e]
C. lusitaniae	S	S	S	S	S	S	S	S to R[f]
Interpretive breakpoints								
Sensitive	≤8	≤0.125	≤0.1	NA	NA	NA	NA	NA
S-DD or I	S-DD: 16–32	S-DD: 0.25–0.5	2	NA	NA	NA	NA	NA
R	>32	>0.5	≤4	NA	NA	NA	NA	NA

[a]Except for amphotericin B, interpretations are based on the use of a broth sensitivity test.
[b]Approximately 15% of *C. glabrata* isolates are resistant to fluconazole.
[c]Approximately 46% of *C. glabrata* isolates and 31% of *C. krusei* isolates are resistant to itraconazole.
[d]Most isolates of *C. parapsilosis* have reduced susceptibility to echinocandins.
[e]A significant proportion of *C. glabrata* and *C. krusei* isolates has reduced susceptibility to amphotericin B.
[f]Although frank resistance to amphotericin B is not observed in all isolates, it is well described for isolates of *C. lusitaniae*.
For antifungal drugs and pathogens for which susceptibility breakpoints have been established (fluconazole, itraconazole, voriconazole):
S = susceptible; S-DD = susceptible-dose dependent (see text); I = intermediate; R = resistant; NA = not available (has not been established for this antifungal against this pathogen).
For antifungal drugs and pathogens for which susceptibility breakpoints have not been established, an estimate of relative activity:
+++ = reliable activity with occasional resistance
++ = moderate activity but resistance is noted
+ = occasional activity
0 = no meaningful activity
Data from NCCLS,[5] Pappas et al.,[7] and Eschenauer et al.[12]

Microbial resistance can refer to *primary* or *secondary* resistance, as determined by in vitro susceptibility testing using standardized methodology. NCCLS resistance breakpoints are based on data relating treatment outcomes and fungal MICs and indicate the MIC at which clinical responses demonstrate a marked decline.[8] However, they do not serve as absolute predictors of therapeutic success or failure.

Primary or *intrinsic resistance* refers to resistance recorded prior to drug exposure in vitro or in vivo. *Secondary* or *acquired resistance* develops on exposure to an antifungal agent and can be either reversible, owing to transient adaptation, or acquired as a result of one or more genetic alterations. The clinical consequences of antifungal resistance can be observed in treatment failures and in changes in the prevalences of *Candida* species

TABLE 130-2 General Patterns of In Vitro Susceptibility of Non-*Candida* Fungal Pathogens[a]

	Patterns of Susceptibility							
	Azoles				*Echinocandins*			*Amphotericin B*
Pathogen	**Fluconazole**	**Itraconazole**	**Voriconazole**	**Posaconazole**	**Caspofungin**	**Micafungin**	**Anidulafungin**	**Amphotericin B**
Aspergillus								
A. fumigatus	No	Yes	Yes	Yes	Yes	Yes	Yes	Yes
A. flavus	No	Yes	Yes	Yes	Yes	Yes	Yes	Yes
A. terreus	No	Yes	Yes		Yes			No
Fusarium	No	No	Yes (but breakthrough infections are seen)	Conflicting data (species dependent)	No	No	No	Yes but occasional resistance
Scedosporium	No	No	Yes	Yes (apiospermum)	No	No	No	No
Zygomycetes[b]	No	No	No	Yes	No	No	No	Yes
Trichosporon	No	No	Yes	Yes	No	No	No	No
Cryptococcus	Yes	Yes	Yes	Yes	No	No	No	
Histoplasma	Yes	Yes	Yes	Yes	No[c]	No[c]	No[c]	Yes
Coccidioides	Yes	Yes	Yes	Yes	No[c]	No[c]	No[c]	Yes

[a]No = has minimal or no in vitro activity versus the pathogen; Yes = possesses adequate in vitro activity versus the pathogen.
[b]Includes *Rhizopus, Mucor, Absidia* species.
[c]While the echinocandins display activity against the mycelial forms of endemic fungi such as *Histoplasma* spp., *Blastomyces* spp., and *Coccidioides* spp., they display significantly higher MIC values against the yeast forms of these organisms, and should not be used to treat these infections.
Data from Eschenauer et al.[12] and Dodds.[78]

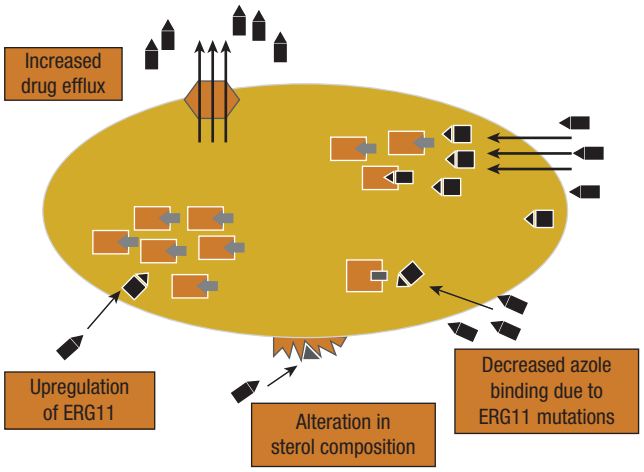

FIGURE 130-2. Mechanisms of azole resistance. Four different mechanisms result in azole resistance: (a) mutations or upregulation of *ERG11*, the target enzyme of azoles, (b) expression of multidrug efflux transport pumps that decrease antifungal drug accumulation within the fungal cell, (c) alteration of the structure or concentration of antifungal drug target proteins, and (d) alteration of membrane sterol proteins.

causing disease. The evidence for the emergence of antifungal-resistant yeasts in patients other than those with HIV infection is confounded by the lack of standardized susceptibility testing methods and definitions of resistance. Large-scale surveys of yeasts from blood cultures, tested by standardized methodology, do not yet suggest that antifungal resistance is a significant or growing therapeutic problem.[8]

A patient may respond clinically to treatment with an antifungal agent despite resistance to that agent in vitro because the patient's own immune system may eradicate the infection, or the agent may reach the site of infection in high concentrations.[8] Resistance to azole antifungal agents has been studied intensively, partly because of the increased number of fluconazole-resistant *Candida* strains isolated from AIDS patients. Resistance can be acquired (i.e., transferred from other organisms or developed during therapy as a result of exposure to the antifungal agent) or intrinsic (innate lack of susceptibility of the antifungal agent to a pathogen). This issue has been reviewed extensively.

The most exhaustive and definitive accounts of antifungal resistance have been described in *Candida* species, in particular *Candida albicans* and, to a lesser extent, *C. glabrata*, *C. tropicalis*, and *C. krusei*, as well as in a few *Cryptococcus neoformans* isolates.[9–11] There are four different mechanisms that result in azole resistance: (a) mutations or upregulation of *ERG11* (an enzyme involved in the ergosterol biosynthesis pathway), (b) expression of multidrug efflux transport pumps that decrease antifungal drug accumulation within the fungal cell, (c) alteration of the structure or concentration of antifungal drug target proteins, and (d) alteration of membrane sterol proteins (Fig. 130–2). It is beyond the scope of this chapter to provide a complete discussion of the biochemical mechanisms of fungal resistance. Interested readers are referred to several excellent reviews concerning this topic.[8–11] Efflux pumps have been identified in *C. albicans, C. glabrata, C. tropicalis*, and *Candida dubliniensis* and appear to be the most common mechanism of resistance encountered in clinical isolates. Some of these mechanisms (efflux pumps in particular) appear to be reversible when selective pressure of antifungal agents is withdrawn.

Even though ketoconazole was used widely for the treatment of mucocutaneous candidiasis, resistant strains appeared very rarely. In patients with the uncommon syndrome of chronic mucocutaneous candidiasis, however, the chronic use of ketoconazole was associated with the emergence of ketoconazole-resistant *C. albicans*. Resistance likely developed in this specific population of patients because of two factors: the chronic use of ketoconazole and the inability of patients with this syndrome to eradicate the organism by normal host defense mechanisms. Fluconazole-resistant *C. albicans* have been noted primarily in AIDS patients, usually after CD4 counts are less than 50 cells/mm^3 and after fluconazole has been used chronically for repeated episodes of thrush over months to years. Resistance develops in a stepwise progression in patients who have repeated episodes of thrush with one or several persisting strains of *C. albicans*.

Among hospitalized patients, there is increasing evidence for a shift toward isolation of other resistant species, such as *C. glabrata* and *C. krusei*, that have moderate or high-level resistance to fluconazole. This phenomenon has been especially common among patients in whom fluconazole has been used extensively.[3]

Resistance has not been described widely with itraconazole. This can be partly related to the fact that the drug has been used primarily for the treatment of endemic mycoses and not candidiasis. Even in patients never treated with itraconazole, however, *C. albicans* strains that are resistant to fluconazole also show decreased susceptibility to itraconazole.

The most commonly reported mechanisms of azole resistance among *C. albicans* isolates include reduced permeability of the fungal cell membrane to azoles, alteration in the target fungal enzymes (cytochrome P450) resulting in decreased binding of the azole to the target site, and overproduction of the fungal cytochrome P450 (CYP) enzymes. Studies also suggest the presence of efflux pumps capable of actively pumping azoles from the target pathogen, thereby conferring multidrug resistance to azole antifungals.[8–11]

C. glabrata is intrinsically more resistant than *C. albicans* to ketoconazole. Several strains of *C. glabrata* have been well characterized in terms of the mechanism of ketoconazole resistance. Decreased permeability to azoles has been described, but other strains show enhanced activity of the P450 cell membrane enzymes as well. *C. krusei* is inherently resistant to fluconazole, but it appears to be more susceptible to the other azoles. Decreased uptake of fluconazole into the fungal cell has been noted for several *C. krusei* strains.[8–11]

Although rare, in vitro intrinsic resistance to amphotericin B is described, mainly in *Candida lusitaniae*, *Candida guilliermondii*, and some molds (*Fusarium* spp. and *Pseudallescheria boydii*).[11] However, the current in vitro M27-A methodology discriminates poorly between rates of susceptibility of *Candida* species to amphotericin B. Although the rate of apparent resistance to amphotericin B appears to be quite low, breakthrough bacteremias in patients treated with amphotericin B have been observed. *C. glabrata*, *C. guilliermondii*, *C. krusei*, and *C. lusitaniae* appear to have a higher propensity than other *Candida* species to develop resistance to amphotericin B; this point should be kept in mind when treating patients with infections caused by one of these pathogens.[8] Because polyenes target ergosterol in the membranes of fungal cells, it is not surprising that amphotericin B–resistant strains of *Candida* generally have a marked decrease in ergosterol content compared with amphotericin B–susceptible strains. Resistant isolates of *Cryptococcus neoformans* have been reported to have a mutation in the C8 isomerization step of ergosterol synthesis.[11]

Although spontaneous resistance of *C. albicans* to echinocandins has been documented in vitro, the specific mechanisms of resistance have not been fully elucidated and prospective worldwide surveillance of clinical *Candida* isolates has revealed no evidence of emerging caspofungin resistance.[12]

PATHOGENESIS AND EPIDEMIOLOGY

Systemic mycoses caused by primary or pathogenic fungi include histoplasmosis, coccidioidomycosis, cryptococcosis, blastomycosis, paracoccidioidomycosis, and sporotrichosis. Primary pathogens can cause disease in both healthy and immunocompromised individuals, although disease generally is more severe or disseminated in the immunocompromised host. In contrast, mycoses caused by opportunistic fungi such as *C. albicans, Aspergillus* species, *Trichosporon, Torulopsis (Candida) glabrata, Fusarium, Alternaria*, and *Mucor* generally are found only in the immunocompromised host.[1]

Most fungal infections are acquired as a result of accidental inhalation of airborne conidia. For example, *Histoplasma capsulatum* is found in soil contaminated by bat, chicken, or starling excreta, and *C. neoformans* is associated with pigeon droppings. Although some fungi, including *C. albicans, C. neoformans*, and *Aspergillus* species, are ubiquitous pathogens with worldwide distribution, other fungi have regional distributions associated with specific geographic environments.[1]

Systemic fungal infections are a major cause of morbidity and mortality in the immunocompromised patient. Fungal infections account for 20% to 30% of fatal infections in patients with acute leukemia, 10% to 15% of fatal infections in patients with lymphoma, and 5% of fatal infections in patients with solid tumors. The frequency of fungal infections among transplant recipients ranges from 0% to 20% for kidney and bone marrow transplant recipients, to 10% to 35% for heart transplant recipients, and 30% to 40% for liver transplant recipients.[4]

Approximately 2% to 4% of all hospitalized patients develop a nosocomial infection. Of these, bacteria comprise the most common etiologic agent.[1] Fungi, however, are becoming increasingly significant nosocomial pathogens. Fungi account for 10% of all bloodstream isolates. *Candida* species (primarily *C. albicans*) are the fourth most commonly isolated bloodstream isolate and account for 78% of all nosocomial fungal infections.[13]

Nosocomially acquired fungal infections can arise from either exogenous or endogenous flora. Endogenous flora can include normal commensal organisms of the skin, gastrointestinal (GI), genitourinary, or respiratory tract. *C. albicans* is found as a normal commensal of the GI tract in 20% to 30% of humans.

A complex interplay of host and pathogen factors influences the acquisition and development of fungal infections. Intact skin or mucosal surfaces serve as primary barriers to infection. Desiccation, epithelial cell turnover, fatty acid content, and low pH of the skin are believed to be important factors in host resistance. Bacterial flora of the skin and mucous membranes compete with fungi for growth. Alterations in the balance of normal flora caused by the use of antibiotics or alterations in nutritional status can allow the proliferation of fungi such as *Candida*, increasing the likelihood of systemic invasion and infection.[1]

The growth of fungi within tissues is restrained by a number of mechanisms. For example, serum has fungistatic activity against *Candida,* in part because of transferrins, the human iron-binding proteins that deprive microbes of the iron needed for synthesis of respiratory enzymes. Serum also contains globulins, which cause a nonimmunologic clumping of *Candida*, facilitating their elimination by inflammatory cells.[1]

Tissue reaction in the presence of fungi varies with fungal species, site of proliferation, and duration of infection. Phagocytosis by neutrophils and macrophages is the earliest mechanism that prevents the establishment of fungi. Consequently, patients with decreased neutrophil counts or decreased neutrophil function are at higher risk of infections, particularly infections caused by *Candida* and *Aspergillus* species. Some mycoses are characterized by a low-grade inflammatory response that does not eliminate the fungi. Fungal cells sometimes can persist within macrophages without being killed, perhaps because of resistance to the effects of lysosomal enzymes.[1]

DIAGNOSIS

2 The diagnosis of invasive fungal infections generally is accomplished by careful evaluation of clinical symptoms, results of serologic tests, and histopathologic examination and culture of clinical specimens. Skin tests generally are not useful diagnostically because they do not distinguish between active and past infection. They remain useful as screening tools and in epidemiologic studies to determine endemic areas. It is beyond the scope of this chapter to discuss the relative merits of each of the immunologic tests used in the diagnosis of invasive fungal infections. Interested readers, however, are referred to several excellent reviews concerning this topic.[14]

TREATMENT

Invasive Mycoses

Strategies for the prevention or treatment of invasive mycoses can be classified broadly as prophylaxis, early empirical therapy, empirical therapy, and secondary prophylaxis or suppression.[1] In patients undergoing cytotoxic chemotherapy, antifungal therapy is directed primarily at the prevention or treatment of infections caused by *Candida* and *Aspergillus* species. Prophylactic therapy with topical, oral, or intravenous antifungal agents is administered prior to and throughout periods of granulocytopenia (absolute neutrophil count <1,000 cells/L). The potential benefits of prophylactic therapy must be weighed against the potential risks inherent in each regimen, including safety, efficacy, cost, the prevalence of infection, and the potential consequences (e.g., resistance) of widespread use.

Early empirical therapy is the administration of systemic antifungal agents at the onset of fever and neutropenia. Empirical therapy with systemic antifungal agents is administered to granulocytopenic patients with persistent or recurrent fever despite the administration of appropriate antimicrobial therapy.

Secondary prophylaxis (or suppressive therapy) is the administration of systemic antifungal agents (generally prior to and throughout the period of granulocytopenia) to prevent relapse of a documented invasive fungal infection that was treated during a previous episode of granulocytopenia.

Although these treatment classifications also have been applied to the treatment of fungal infections in AIDS, patients with AIDS rarely acquire systemic infections caused by *Candida* or *Aspergillus* species unless they become granulocytopenic because of disease or drugs. The use of antifungal prophylaxis is much less widely studied in this population, although studies suggest that early antifungal prophylaxis with fluconazole or itraconazole decreases the incidence of invasive cryptococcal disease among adult patients who have advanced HIV disease and severe immune suppression (CD4 count <50 cells/mm^3). However, neither of these interventions showed a clear effect on mortality.[15] Suppressive therapy generally is necessary following acute therapy for histoplasmosis, coccidioidomycosis, and cryptococcosis because of the high rates of relapse when antifungal therapy is discontinued.

PROPHYLAXIS OF FUNGAL INFECTION IN THE HIV-INFECTED PATIENT

The use of antifungal prophylaxis to prevent fungal infections in HIV-infected patients has been assessed. Fluconazole prevented cryptococcosis and local *Candida* infections, including esophagitis, in HIV-infected patients, but overall mortality was not improved. Because of the high costs of long-term prophylaxis, improved therapeutic regimens available for treating cryptococcal meningitis, and increasing reports of fluconazole resistance among *Candida* isolates from AIDS patients, many clinicians prefer not to use fluconazole prophylaxis in AIDS patients. For some patients with very low CD4 counts (<50 cells/microliter), however, some clinicians feel that it is cost-effective to use fluconazole prophylaxis (100 to 200 mg daily) to prevent cryptococcosis. In endemic areas where the incidence of histoplasmosis is 110 cases per 100 patient-years, prophylaxis with itraconazole (200 mg daily orally) is recommended in HIV-infected patients with CD4 cell counts <150 cells/mm^3.

HISTOPLASMOSIS

In humans, histoplasmosis is caused by inhalation of dust-borne microconidia of the dimorphic fungus *H. capsulatum*. Although there exist two dimorphic varieties of *H. capsulatum*, the small-celled (2–5 microns) form (var. *capsulatum*) occurs globally, whereas the large-celled (8–15 microns) form (var. *duboisii*) is confined to the African continent and Madagascar. In tissues stained by conventional techniques, *H. capsulatum* appears as an oval or round, narrow-pore, budding, unencapsulated yeast.[16]

EPIDEMIOLOGY

3 Although histoplasmosis is found worldwide, certain areas of North and Central America are recognized as endemic areas. In the United States, most disease is localized along the Ohio and Mississippi River valleys, where more than 90% of residents may be affected. Precise reasons for this endemic distribution pattern are unknown but are thought to include moderate climate, humidity, and soil characteristics. *H. capsulatum* is found in nitrogen-enriched soils, particularly those heavily contaminated by avian or bat guano, which accelerates sporulation. Blackbird or pigeon roosts, chicken coops, and sites frequented by bats, such as caves, attics, or old buildings, serve as "microfoci" of infections; once contaminated, soils yield *Histoplasma* for many years. Although birds are not infected because of their high body temperature, bats (mammals) may be infected and can pass yeast forms in their feces, allowing the spread of *H. capsulatum* to new habitats. Air currents carry the spores for great distances, exposing individuals who were unaware of contact with the contaminated site.[16–18]

PATHOPHYSIOLOGY

At ambient temperatures, *H. capsulatum* grows as a mold. The mycelial phase consists of septate branching hyphae with terminal micro- and macroconidia that range in size from 2 to 14 microns in diameter. When soil is disturbed, these conidia become aerosolized and reach the bronchioles or alveoli.[16]

Animal studies demonstrate that within 2 to 3 days after reaching lung tissue, the conidia germinate, releasing yeast forms that begin multiplying by binary fission. During the next 9 to 15 days, organisms are ingested but not destroyed by large numbers of macrophages that are recruited to the infected site, resulting in small infiltrates. Infected macrophages migrate to the mediastinal lymph nodes and other sites within the mononuclear phagocyte system, particularly the spleen and liver. At this time, the onset of specific T-cell immunity in the nonimmune host activates the macrophages, rendering them capable of fungicidal activity. Tissue granulomas form, many of which develop central caseation and necrosis over the next 2 to 4 months. Over a period of several years, these foci become encapsulated and calcified, often with viable yeast trapped within the necrotic tissue.[16,19]

Cellular immunity, as measured by histoplasmin skin-test reactivity, wanes in the absence of occasional reexposure. Although exposure to heavy inocula can overcome these immune mechanisms, resulting in severe disease, reinfection occurs frequently in endemic areas. In the immune individual, the reactions of acquired immunity begin 24 to 48 hours after the appearance of yeast forms, resulting in milder forms of illness and little proliferation of organisms. Although viable organisms can be found within granulomas years after initial infection, the organisms appear to have little ability to proliferate within the fibrous capsules, except in immunocompromised patients.[16,19]

CLINICAL PRESENTATION[15,16,18,19]

General

The outcome of infection with *H. capsulatum* depends on a complex interplay of host, pathogen, and environmental factors. Host factors include the degree of immunosuppression and the presence of immunity (from prior infection). Environmental factors include inoculum size, exposure within an enclosed area, and duration of exposure. Hematogenous dissemination from the lungs to other tissues probably occurs in all infected individuals during the first 2 weeks of infection before specific immunity has developed but is nonprogressive in most cases, which leads to the development of calcified granulomas of the liver and/or spleen. Progressive pulmonary infection is common in patients with underlying centrilobular emphysema.

Acute and chronic manifestations of histoplasmosis appear to result from unusual inflammatory or fibrotic responses to the pathogen, including pericarditis and rheumatologic syndromes during the first year after exposure, with chronic mediastinal inflammation or fibrosis, broncholithiasis, and enlarging parenchymal granulomas later in the course of disease.

Acute Pulmonary Histoplasmosis

In the vast majority of patients, low-inoculum exposure to *H. capsulatum* results in mild or asymptomatic pulmonary histoplasmosis. The course of disease generally is benign, and symptoms usually abate within a few weeks of onset. Patients exposed to a higher inoculum during an acute primary infection or reinfection can experience an acute, self-limited illness with flu-like pulmonary symptoms, including fever, chills, headache, myalgia, and a nonproductive cough. Patients with diffuse pulmonary histoplasmosis can have diffuse radiographic involvement, become hypoxic, and require ventilatory support. A low percentage of patients present with arthritis, erythema nodosum, pericarditis, or mediastinal granuloma.

Chronic Pulmonary Histoplasmosis

Chronic pulmonary histoplasmosis generally presents as an opportunistic infection imposed on a preexisting structural abnormality, such as lesions resulting from emphysema. Patients demonstrate chronic pulmonary symptoms and apical lung lesions that progress with inflammation, calcified granulomas, and fibrosis. Patients with early, noncavitary disease often recover without treatment. Progression of disease over a period of years, seen in 25% to 30% of

patients, is associated with cavitation, bronchopleural fistulas, extension to the other lung, pulmonary insufficiency, and often death.

Disseminated Histoplasmosis

In patients exposed to a large inoculum and in immunocompromised hosts, successful containment of the organism within macrophages may not occur, resulting in a progressive illness characterized by yeast-filled phagocytic cells and an inability to produce granulomas. This disease, termed *disseminated histoplasmosis*, is characterized by persistent parasitization of macrophages. The clinical severity of the diverse forms of disseminated histoplasmosis (Table 130–3) generally parallels the degree of macrophage parasitization observed.

Acute (infantile) disseminated histoplasmosis is characterized by massive involvement of the mononuclear phagocyte system by yeast-engorged macrophages. Classically, this severe type of infection is seen in infants and young children and (rarely) in adults with Hodgkin disease or other lymphoproliferative disorders. In infants or children, acute disseminated histoplasmosis is characterized by unrelenting fever, anemia, leukopenia or thrombocytopenia, enlargement of the liver, spleen, and visceral lymph nodes, and GI symptoms, particularly nausea, vomiting, and diarrhea. The chest roentgenogram often demonstrates remnants of the initiating acute pulmonary lesion. Untreated disease is uniformly fatal in 1 to 2 months. A less severe "subacute" form of the disease, which occurs in both infants and immunocompetent adults, is characterized by focal destructive lesions in various organs, weight loss, weakness, fever, and malaise. Untreated disease generally is fatal in approximately 10 months.

Most adults with disseminated histoplasmosis demonstrate a mild, chronic form of the disease. Untreated patients often are ill for 10 to 20 years, demonstrating long asymptomatic periods interrupted by relapses of clinical illness characterized primarily by weight loss, weakness, and fatigue. Chronic disseminated histoplasmosis can be seen in patients with lymphoreticular neoplasms (Hodgkin disease) and patients undergoing immunosuppressant chemotherapy for organ transplantation or for rheumatic diseases. Although CNS involvement occurs in 10% to 20% of patients with severe underlying immunosuppressive conditions, focal organ involvement is uncommon. The disease is characterized by the development of focal granulomatous lesions, often with bone marrow involvement resulting in thrombocytopenia, anemia, and leukemia. Fever, hepatosplenomegaly, and GI ulceration are common.

Histoplasmosis in HIV-Infected Patients

Adult patients with AIDS demonstrate an acute form of disseminated disease that resembles the syndrome seen in infants and children. Progressive disseminated histoplasmosis (PDH), which is defined as a clinical illness that does not improve after at least 3 weeks of observation and that is associated with physical or radiographic findings and/or laboratory evidence of involvement of extrapulmonary tissues, can occur as the direct result of initial infection or because of the reactivation of dormant foci. In endemic areas, 50% of AIDS patients demonstrate PDH as the first manifestation of their disease. PDH is characterized by fever (75% of patients), weight loss, chills, night sweats, enlargement of the spleen, liver, or lymph nodes, and anemia. Pulmonary symptoms occur in only one third of patients and do not always correlate with the presence of infiltrates on chest roentgenogram. A clinical syndrome resembling septicemia is seen in approximately 25% to 50% of patients.[19]

DIAGNOSIS

Detection of single, yeastlike cells 2 to 5 microns in diameter with narrow-based budding by direct examination or by histologic study of blood smears or tissues should raise strong suspicion of infection with *H. capsulatum* because colonization does not occur as with *Aspergillus* or *Candida* infection. Identification of mycelial isolates from clinical cultures can be made by conversion of the mycelium to the yeast form (requires 3 to 6 weeks) or through a rapid (2-hour) and 100% sensitive chemiluminescent DNA probe that recognizes ribosomal DNA. In patients with suspected disseminated or chronic cavitary histoplasmosis, 2 to 3 blood, sputum, and bone marrow cultures and stains should be obtained using the lysis centrifugation (Isolator tube) technique, and the cultures should be held for 14 to 21 days for optimal yield of *H. capsulatum*. In patients with acute self-limited histoplasmosis, extensive testing to verify the diagnosis may not be necessary.

In most patients, serologic evidence remains the primary method in the diagnosis of histoplasmosis. Results obtained from commercially available complement fixation (CF), immunodiffusion (ID), and latex agglutination (LA) antibody tests are used alone or in combination. In general, the use of histoplasmin skin tests is of little value except in epidemiologic studies because histoplasmin reactivity waxes in the absence of occasional reexposure. In addition, histoplasmin skin testing can result in a false increase in the CF titer for mycelial antigen (CF-M) to *H. capsulatum*. A fourfold rise in the CF titer is usually indicative of recent infection, although some patients with severe disease or profound immunosuppression can demonstrate a weaker antibody response. CF titers remain positive for many years, since CF antibodies persist after infection. Because the ID test is more specific but less sensitive than CF, it should be used to assess the importance of weakly reactive results obtained by CF rather than as a screening procedure.

In the AIDS patient with PDH, the diagnosis is best established by bone marrow biopsy and culture, which yield positive cultures in more than 90% of patients, although blood cultures and histopathologic examination and culture of pulmonary tissue, sputum, skin, and lymph nodes also can be helpful. Detection of *H. capsulatum* polysaccharide antigen (HPA) in urine, blood, or cerebrospinal fluid (CSF) by enzyme-linked immunosorbent assay (ELISA) or by modified RIA offer promising new techniques for the rapid diagnosis of histoplasmosis. The HPA (RIA) levels also have been used successfully to monitor the course of therapy and to detect relapses in patients with AIDS, and the clearance of antigen from serum and urine correlates with clinical efficacy during maintenance therapy with itraconazole.[19]

TREATMENT

Histoplasmosis

NON–HIV-INFECTED PATIENT

4 Table 130–3 summarizes the recommended therapy for the treatment of histoplasmosis. In general, asymptomatic or mildly ill patients and patients with sarcoid-like disease do not benefit from antifungal therapy. In the vast majority of patients, low-inoculum exposure to *H. capsulatum* results in *mild* or *asymptomatic* pulmonary histoplasmosis. The course of disease generally is benign, and symptoms usually abate within a few weeks of onset. Therapy can be helpful in symptomatic patients whose conditions have not improved during the first month of infection. Fever persisting more than 3 weeks can indicate that the patient is developing progressive disseminated disease, which can be aborted by antifungal therapy. Whether antifungal therapy hastens recovery or prevents complications is unknown because it has never been studied in prospective trials.

Fluconazole remains a second-line agent for the treatment of histoplasmosis. Clinical data regarding the use of newer azoles such as voriconazole and posaconazole are limited. While both

TABLE 130-3 Clinical Manifestations and Therapy of Histoplasmosis

Type of Disease and Common Clinical Manifestations	Approximate Frequency (%)[a]	Therapy/Comments
Nonimmunosuppressed host		
Acute pulmonary histoplasmosis		
Asymptomatic or mild-moderate disease	50–99	*Asymptomatic, mild, or symptoms <4 weeks:* No therapy generally required. Itraconazole (200 mg 3 times daily for 3 days and then 200 mg once or twice daily for 6–12 weeks) is recommended for patients who continue to have symptoms for 11 months *Symptoms >4 weeks:* Itraconazole 200 mg once daily × 6–12 weeks[b]
Self-limited disease	1–50	*Self-limited disease:* Amphotericin B[c] 0.3–0.5 mg/kg/day × 2–4 weeks (total dose 500 mg) or ketoconazole 400 mg orally daily × 3–6 months can be beneficial in patients with severe hypoxia following inhalation of large inocula; Antifungal therapy generally not useful for arthritis or pericarditis; NSAIDs or corticosteroids can be useful in some cases
Mediastinal granulomas	1–50	Most lesions resolve spontaneously; surgery or antifungal therapy with amphotericin B 40–50 mg/day × 2–3 weeks or itraconazole 400 mg/day orally × 6–12 months can be beneficial in some severe cases; mild to moderate disease can be treated with itraconazole for 6–12 months
Moderately severe-severe diffuse pulmonary disease		Lipid amphotericin B 3–5 mg/kg/day followed by itraconazole 200 mg twice daily for 3 days then twice daily for a total of 12 weeks of therapy; Alternatively, in patients at low risk for nephrotoxicity, amphotericin B deoxycholate 0.7–1 mg/kg/day can be utilized; Methylprednisolone (0.5–1.0 mg/kg daily IV) during the first 1–2 weeks of antifungal therapy is recommended for patients who develop respiratory complications, including hypoxemia or significant respiratory distress
Inflammatory/fibrotic disease	0.02	*Fibrosing mediastinitis:* The benefit of antifungal therapy (itraconazole 200 mg twice daily × 3 months) is controversial but should be considered, especially in patients with elevated ESR or CF titers ≤1:32; surgery can be of benefit if disease is detected early; late disease cannot respond to therapy *Sarcoid-like:* NSAIDs or corticosteroids[d] can be of benefit for some patients *Pericarditis:* Severe disease: corticosteroids 1 mg/kg/day or pericardial drainage procedure
Chronic cavitary pulmonary histoplasmosis	0.05	Antifungal therapy generally recommended for all patients to halt further lung destruction and reduce mortality *Mild–moderate disease:* Itraconazole (200 mg 3 times daily for 3 days and then 1 or 2 times daily for at least 1 year; Some clinicians recommend therapy for 18–24 months due to the high rate of relapse; Itraconazole plasma concentrations should be obtained after the patient has been receiving this agent for at least 2 weeks *Severe disease:* Amphotericin B 0.7 mg/kg/day for a minimum total dose of 25-35 mg/kg is effective in 59–100% of cases and should be used in patients who require hospitalization or are unable to take itraconazole because of drug interactions, allergies, failure to absorb drug, or failure to improve clinically after a minimum of 12 weeks of itraconazole therapy
Histoplasma endocarditis		Amphotericin B (lipid formulations may be preferred, due to their lower rate of renal toxicity) plus a valve replacement is recommended; If the valve cannot be replaced, lifelong suppression with itraconazole is recommended
Central nervous system histoplasmosis		Amphotericin B should be used as initial therapy (lipid formulations at 5 mg/kg/day, for a total dosage of 175 mg/kg may be preferred, due to their lower rate of renal toxicity) for 4–6 weeks, followed by an oral azole (fluconazole or itraconazole 200 mg 2 or 3 times daily) for at least a year; Some patients may require lifelong therapy; Response to therapy should be monitored by repeat lumbar punctures to assess *Histoplasma* antigen levels, WBC, and CF antibody titers; Blood levels of itraconazole should be obtained to ensure adequate drug exposure
Immunosuppressed host		
Disseminated histoplasmosis	0.02 – 0.05	*Disseminated histoplasmosis:* Untreated mortality 83–93%; relapse 5– 23% in non-AIDS patients; therapy is recommended for all patients
Acute (Infantile) Subacute		*Nonimmunosuppressed patients:* Ketoconazole 400 mg/day orally × 6–12 months or amphotericin B 35 mg/kg IV *Immunosuppressed patients (non-AIDS) or endocarditis or CNS disease:* Amphotericin B >35 mg/kg × 3 months followed by fluconazole or itraconazole 200 mg orally twice daily × 12 months
Progressive histoplasmosis (immunocompetent patients and immunosuppressed patients without AIDS)		*Moderately severe to severe:* Liposomal amphotericin B (3.0 mg/kg daily), amphotericin B lipid complex (5.0 mg/kg daily), or deoxycholate amphotericin B (0.7–1.0 mg/kg daily) for 1–2 weeks, followed by itraconazole (200 mg twice daily for at least 12 months) *Mild to moderate:* Itraconazole (200 mg twice daily for at least 12 months)
Progressive disease of AIDS	25–50[e]	Amphotericin B 15–30 mg/kg (1–2 g over 4–10 weeks)[f] or itraconazole 200 mg three times daily for 3 days then twice daily for 12 weeks, followed by lifelong suppressive therapy with itraconazole 200–400 mg orally daily; Although patients receiving secondary prophylaxis (chronic maintenance therapy) might be at low risk for recurrence of systemic mycosis when their CD4+ T-lymphocyte counts increase to >100 cells/microliter in response to HAART, the number of patients who have been evaluated is insufficient to warrant a recommendation to discontinue prophylaxis

AIDS, acquired immunodeficiency syndrome; CF, complement fixation; ESR, erythrocyte sedimentation rate; HAART, highly active antiretroviral therapy; NSAIDs, nonsteroidal antiinflammatory drugs; PO, orally.

[a]As a percentage of all patients presenting with histoplasmosis.

[b]Itraconazole plasma concentrations should be measured during the second week of therapy to ensure that detectable concentrations have been achieved. If the concentration is below 1 mcg/mL, the dose may be insufficient or drug interactions can be impairing absorption or accelerating metabolism, requiring a change in dosage. If plasma concentrations are greater than 10 mcg/mL, the dosage can be reduced.

[c]Desoxycholate amphotericin B.

[d]Effectiveness of corticosteroids is controversial.

[e]As a percentage of AIDS patients presenting with histoplasmosis as the initial manifestation of their disease.

[f]Liposomal amphotericin B (AmBisome) may be more appropriate for disseminated disease.

Data from Deepe,16 Wheat et al.,[18] and Wheat and Kauffman.[19]

have activity against *Histoplasma*, posaconazole appears to be more active than itraconazole in the immune compromised and nonimmune compromised mouse model of infection, while voriconazole has not been tested in animal models. Both agents have been used successfully in a few patients. Of note, the echinocandins have no activity against *Histoplasma*.

Patients with mild, self-limited disease, chronic disseminated disease, or chronic pulmonary histoplasmosis who have no underlying immunosuppression usually can be treated with either oral itraconazole or IV amphotericin B. The goals of therapy are resolution of clinical abnormalities, prevention of relapse, and eradication of infection whenever possible, although chronic suppression of infection can be adequate in immunosuppressed patients, including those with HIV disease.[18,19] Patients with arthritis, erythema nodosum, pericarditis, or mediastinal granuloma can require the addition of a 2-week course of corticosteroids to their therapy.[16]

HIV-INFECTED PATIENT

In AIDS patients, intensive 12-week primary antifungal therapy (induction and consolidation therapy) is followed by lifelong suppressive (maintenance) therapy with itraconazole. Amphotericin B dosages of 50 mg/day (up to 1 mg/kg per day) should be administered intravenously to a cumulative dose of 15 to 35 mg/kg (1 to 2 g) in patients who require hospitalization. Amphotericin B can be replaced with itraconazole 200 mg orally twice daily when the patient no longer requires hospitalization or intravenous therapy to complete a 12-week total course of induction therapy. In patients who do not require hospitalization, itraconazole therapy for 12 weeks can be used.

Fluconazole 800 mg/day orally as induction, followed by 400 mg/day, was effective in 88% of patients, but relapses occurred in approximately one third of patients, and in vitro resistance developed in approximately 50% of patients who relapsed.

In regions experiencing high rates of histoplasmosis (>5 cases/100 patient years), itraconazole 200 mg/day is recommended as prophylactic therapy in HIV-infected patients. Fluconazole is not an acceptable alternative because of its inferior activity against *H. capsulatum* and its lower efficacy for the treatment of histoplasmosis.[18]

Although patients receiving secondary prophylaxis (chronic maintenance therapy) might be at low risk for recurrence of systemic mycosis when their CD4+ T lymphocyte counts increase to >100 cells/microliter in response to highly active antiretroviral therapy (HAART), the number of patients who have been evaluated is insufficient to warrant a recommendation to discontinue prophylaxis.

EVALUATION OF THERAPEUTIC OUTCOMES

Response to therapy should be measured by resolution of radiologic, serologic, and microbiologic parameters and by improvement in signs and symptoms of infection. Although investigators are limited by the lack of standardized criteria to quantify the extent of infection, degree of immunosuppression, or treatment response, response rates (based on resolution or improvement in presenting signs and symptoms) of greater than 80% have been reported in case series in AIDS patients receiving varied dosages of amphotericin B. Rapid responses are reported, with the resolution of symptoms in 25% and 75% of patients by days 3 and 7 of therapy, respectively.

After the initial course of therapy for histoplasmosis is complete, lifelong suppressive therapy with oral azoles or amphotericin B (1 to 1.5 mg/kg weekly or biweekly) is recommended because of the frequent recurrence of infection.[20] Relapse rates in AIDS patients not receiving maintenance therapy range from 50% to 90%.[18]

Antigen testing can be useful for monitoring therapy in patients with disseminated histoplasmosis. Antigen concentrations decrease with therapy and increase with relapse. Some investigators recommend that treatment should continue until antigen concentrations revert to negative or less than 4 units. If treatment is discontinued before antigen concentrations in serum and urine revert to negative, patients should be followed closely for relapse, and antigen levels should be monitored every 3 to 6 months until they become negative.[18]

BLASTOMYCOSIS

North American blastomycosis is a systemic fungal infection caused by *Blastomyces dermatitidis*, a dimorphic fungus that infects primarily the lungs. Patients, however, can present with a variety of pulmonary and extrapulmonary clinical manifestations. Pulmonary disease can be acute or chronic and can mimic infection with tuberculosis, pyogenic bacteria, other fungi, or malignancy. Blastomycosis can disseminate to virtually every other body organ, and approximately 40% of patients with blastomycosis present with skin, bone and joint, or genitourinary tract involvement without any evidence of pulmonary disease.[21]

Pulmonary infection probably occurs by inhalation of conidia, which convert to the yeast form in the lung. A vigorous inflammatory response ensues, with neutrophilic recruitment to the lungs followed by the development of cell-mediated immunity and the formation of noncaseating granulomas.

EPIDEMIOLOGY

Blastomycosis was renamed *North American blastomycosis* in 1942, when Conant and Howell named a similar fungus endemic to South America, *Blastomyces braziliensis*, and the disease it caused *South American blastomycosis*. Although the disease is now recognized to be endemic to the southeastern and south central states of the United States (especially those bordering on the Mississippi and Ohio River basins) and the midwestern states and Canadian provinces bordering the Great Lakes, numerous cases of North American blastomycosis have been diagnosed in Africa, northern parts of South America, India, and Europe. Endemic areas have been defined primarily by analysis of sporadic cases and epidemics or clusters of disease because the lack of a dependable skin or laboratory test makes wide-scale epidemiologic testing to determine the incidence of infection unfeasible at present.[19,20] Although initial review of sporadic cases suggested that males with outdoor occupations that exposed them to soil were at greatest risk for blastomycosis, there is no sex, age, or occupational predilection for blastomycosis.[19,21]

Although *B. dermatitidis* generally is considered to be a soil inhabitant, attempts to isolate the organism in nature frequently have been unsuccessful. *B. dermatitidis* has been isolated from soil containing decayed vegetation, decomposed wood, and pigeon manure, frequently in association with warm, moist soil of wooded areas that is rich in organic debris.[19,21]

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION[13,19,21]

General

Colonization does not occur with *Blastomyces*. *Acute pulmonary blastomycosis* generally is an asymptomatic or self-limited disease characterized by fever, shaking chills, and productive, purulent cough, with or without hemoptysis, in immunocompetent

individuals. The clinical presentation can be difficult to differentiate from other respiratory infections, including bacterial pneumonia, on the basis of clinical symptoms alone.

Sporadic (nonepidemic) pulmonary blastomycosis can present as a more chronic or subacute disease, with low-grade fever, night sweats, weight loss, and productive cough that resembles tuberculosis rather than bacterial pneumonia. *Chronic pulmonary blastomycosis* is characterized by fever, malaise, weight loss, night sweats, chest pain, and productive cough. Patients often are thought to have tuberculosis and frequently have evidence of disseminated disease that can appear 1 to 3 years after the primary pneumonia has resolved. Reactivation of disease can occur in the lungs or as the focus of new infection in other organs.

In approximately 40% of patients, dissemination is not accompanied by reactivation of pulmonary disease. The most common sites for disseminated disease include the skin and bony skeleton, although less commonly the prostate, oropharyngeal mucosa, and abdominal viscera are involved. CNS disease, while exceedingly uncommon, is associated with the highest mortality rate.

Laboratory and Diagnostic Tests

The simplest and most successful method of diagnosing blastomycosis is by direct microscopic visualization of the large, multinucleated yeast with single, broad-based buds in sputum or other respiratory specimens following digestion of cells and debris with 10% potassium hydroxide. Histopathologic examination of tissue biopsies and culture of secretions also should be used to identify *B. dermatitidis*, although it can require up to 30 days to isolate and identify a small inoculum.

No reliable skin test exists to determine the incidence and prevalence of disease in endemic populations, and reliable serologic diagnosis of blastomycosis has long been hampered by the lack of specific and standardized reagents. Serologic response does not always correlate with clinical improvement, although some investigators have noted that a decline in the number of precipitins or CF titers can offer evidence of a favorable prognosis in patients with established disease.

Acute pulmonary blastomycosis generally is an asymptomatic or self-limited disease characterized by fever, shaking chills, and productive, purulent cough, with or without hemoptysis, in immunocompetent individuals. The clinical presentation can be difficult to differentiate from other respiratory infections, including bacterial pneumonia, on the basis of clinical symptoms alone. Sporadic (nonepidemic) cases of pulmonary blastomycosis can present as a more chronic or subacute disease with low-grade fever, night sweats, weight loss, and productive cough that resembles tuberculosis rather than bacterial pneumonia.

TREATMENT

Blastomycosis

NON–HIV-INFECTED PATIENT

5 In patients with mild pulmonary blastomycosis, the clinical presentation of the patient, the immune competence of the patient, and the toxicity of the antifungal agents are the main determinants of whether or not to administer antifungal therapy. All immunocompromised patients and patients with progressive pulmonary disease or with extrapulmonary disease should be treated (Table 130–4). In the case of disease limited to the lungs, cure might have occurred without treatment before the diagnosis is made. Regardless of whether or not the patient receives treatment, however, he or she

TABLE 130-4 Therapy of Blastomycosis

Type of Disease	Preferred Treatment	Comments
Pulmonary[a]		
Life-threatening	Amphotericin B[b] IV 0.7–1 mg/kg/day IV (total dose 1.5–2.5 g)	Patients can be initiated on amphotericin B and changed to oral itraconazole 200–400 mg orally daily once patient is clinically stabilized and a minimum dose of 500 mg of amphotericin B has been administered
Mild to moderate	Itraconazole 200 mg orally twice daily × ≥ 6 months[c]	*Alternative therapy:* Ketoconazole 400–800 mg orally daily × ≥6 months or fluconazole 400–800 mg orally daily × ≥6 months[d] *In patients intolerant of azoles or in whom disease progresses during azole therapy:* Amphotericin B 0.5–0.7 mg/kg/day IV (total dose 1.5–2.5 g)
Disseminated or extrapulmonary		
CNS	Amphotericin B 0.7–1 mg/kg/day IV (total dose 1.5–2.5 g)	For patients unable to tolerate a full course of amphotericin B, consider lipid formulations of amphotericin B or fluconazole ≥ 800 mg orally daily
Non-CNS		
Life-threatening	Amphotericin B 0.7–1 mg/kg/day IV (total dose 1.5–2.5 g)	Patients can be initiated on amphotericin B and changed to oral itraconazole 200–400 mg orally daily once stabilized
Mild to moderate	Itraconazole 200–400 mg orally daily × ≥ 6 months	Ketoconazole 400–800 mg orally daily or fluconazole 400–800 mg orally daily × ≥ 6 months *In patients intolerant of azoles or in whom disease progresses during azole therapy:* Amphotericin B 0.5–0.7 mg/kg/day IV (total dose 1.5–2.5 g) *Bone disease:* Therapy with azoles should be continued for 12 months
Immunocompromised host (including patients with AIDS, transplants, or receiving chronic glucocorticoid therapy)		
Acute disease	Amphotericin B 0.7–1 mg/kg/day IV (total dose 1.5–2.5 g)	Patients without CNS infection can be switched to itraconazole once clinically stabilized and a minimum dose of 1 g of amphotericin B has been administered; long-term suppressive therapy with an azole is advised
Suppressive therapy	Itraconazole 200–400 mg orally daily	For patients with CNS disease or those intolerant of itraconazole, consider fluconazole 800 mg orally daily

AIDS, acquired immunodeficiency syndrome.
[a]Some patients with acute pulmonary infection can have a spontaneous cure. Patients with progressive pulmonary disease should be treated.
[b]Desoxycholate amphotericin B.
[c]In patients not responding to 400 mg, dosage should be increased by 200 mg increments every 4 weeks to a maximum of 800 mg daily.
[d]Therapy with ketoconazole is associated with relapses, and fluconazole therapy achieves a lower response rate than itraconazole.
Data from Wheat and Kauffman[19] and O'Shaughnessy et al.[21]

must be followed carefully for many years for evidence of reactivation or progressive disease.[19,21]

Some authors recommend ketoconazole therapy for the treatment of self-limited pulmonary disease, with the hope of preventing late extrapulmonary disease; however, data supporting the efficacy of these regimens are lacking.[19,21] Itraconazole 200 to 400 mg/day demonstrated 90% efficacy as a first-line agent in the treatment of non–life-threatening non-CNS blastomycosis, and for compliant patients who completed at least 2 months of therapy, a success rate of 95% was noted. No therapeutic advantage was noted with the higher (400 mg) dosage as compared with patients treated with 200 mg.

All patients with disseminated blastomycosis, as well as those with extrapulmonary disease, require therapy. Ketoconazole 400 mg/day orally for 6 months cures more than 80% of patients with chronic pulmonary and nonmeningeal disseminated blastomycosis. Amphotericin B is more efficacious but more toxic and therefore is reserved for noncompliant patients and patients with overwhelming or life-threatening disease, CNS infection, and treatment failures. Cumulative amphotericin B dosages of more than 1 g have resulted in cure without relapse in 70% to 91% of patients with blastomycosis. Relapse rates depend on the total dosage of amphotericin B administered.[19,21] Patients with genitourinary tract disease should be treated initially with 600–800 mg/day of ketoconazole because of the low concentrations of drug achieved in the urine and prostate tissue.

Patients should be monitored carefully for signs of clinical failure, and those who fail or are unable to tolerate itraconazole therapy or who develop CNS disease should be treated with amphotericin B for a total cumulative dose of 1.5 to 2.5 g.[19,21]

Lipid preparations of amphotericin B are effective in animal models of blastomycosis, but they have not been evaluated adequately in humans. Limited clinical experience suggests that these preparations can provide an alternative for patients unable to experience standard therapy with amphotericin B because of toxicity. Surgery has only a limited role in the treatment of blastomycosis.

HIV-INFECTED PATIENT

For unclear reasons, blastomycosis is an uncommon opportunistic disease among immunocompromised individuals, including AIDS patients; however, blastomycosis can occur as a late (CD4 lymphocytes <200 cells/mm^3) and frequently fatal complication of HIV infection. In this population, overwhelming disseminated disease with frequent involvement of the CNS is common.[19] Following induction therapy with amphotericin B (total cumulative dose of 1 g), HIV-infected patients should receive chronic suppressive therapy with an oral azole antifungal. Despite its higher cost, itraconazole has become the drug of choice for non–life-threatening histoplasmosis (mild to moderate disease) in HIV-infected patients.[21]

COCCIDIOIDOMYCOSIS

EPIDEMIOLOGY

Coccidioidomycosis is caused by infection with *Coccidioides immitis*, a dimorphic fungus found in the southwestern and western United States, as well as in parts of Mexico and South America. In North America, the endemic regions encompass the semiarid areas of the southwestern United States from California to Texas known as the Lower Sonoran Zone, where there is scant annual rainfall, hot summers, and sandy, alkaline soil. *Coccidioides immitis* grows in the soil as a mold, and mycelia proliferate during the rainy season.

TABLE 130-5 Risk Factors for Severe, Disseminated Infection with Coccidioidomycosis

Race (Filipinos > African-Americans > Native Americans > Hispanics > Asians)
Pregnancy (especially when infection is acquired or reactivated in the second or third trimester)
Compromised cellular immune system, including
AIDS patients
Patients receiving
Corticosteroids
Immunosuppressive agents
Chemotherapy
Male gender
Neonates
Patients with B or AB blood types

AIDS, acquired immune deficiency syndrome.
Data from Galgiani JM, Ampel NM, Blair JE, Catanzaro A, et al. Practice guidelines for the treatment of coccidioidomycoses. Clin Infect Dis 2005;30:658–661.

During the dry season, resistant arthroconidia form and become airborne when the soil is disturbed.

Although generally considered to be a regional disease, coccidioidomycosis has increased in importance in recent years because of the increased tourism and population in endemic areas, the increased use of immunosuppressive therapy in transplantation and oncology, and the AIDS epidemic. Although there is no racial, hormonal, or immunologic predisposition for acquiring primary disease, these factors affect the risk of subsequent dissemination of disease (Table 130–5).[20]

PATHOPHYSIOLOGY

When individuals come in contact with contaminated soil during ranching, dust storms, or proximity to construction sites or archaeologic excavations, arthroconidia are inhaled into the respiratory tree, where they transform into spherules, which reproduce by cleavage of the cytoplasm to produce endospores. The endospores are released when the spherules reach maturity. Similar to histoplasmosis, an acute inflammatory response in the tissue leads to infiltration of mononuclear cells, ultimately resulting in granuloma formation.[20]

CLINICAL PRESENTATION OF COCCIDIOIDOMYCOSIS[11,19–22]

Coccidioidomycosis encompasses a spectrum of illnesses ranging from primary uncomplicated respiratory tract infection that resolves spontaneously to progressive pulmonary or disseminated infection. Initial or primary infection with *C. immitis* almost always involves the lungs. Although approximately one third of the population in endemic areas is infected, the average incidence of symptomatic disease is only approximately 0.43%.

Signs and Symptoms

In *asymptomatic disease* (60% of patients), patients have nonspecific symptoms that are often indistinguishable from ordinary upper respiratory infections, including fever, cough, headache, sore throat, myalgias, and fatigue. A fine, diffuse rash can appear during the first few days of the illness. Primary pneumonia can be the first manifestation of disease, characterized by a productive cough that can be blood-streaked, as well as single or multiple soft or dense homogeneous hilar or basal infiltrates on chest roentgenogram. Chronic, persistent pneumonia or persistent pulmonary coccidioidomycosis (primary disease lasting more than 6 weeks) is complicated by hemoptysis, pulmonary scarring, and the formation of cavities or bronchopleural fistulas.

Necrosis of pulmonary tissue with drainage and cavity formation occurs commonly. Most parenchymal cavities close spontaneously or form dense nodular scar tissue that can become superinfected with bacteria or spherules of *C. immitis*. These patients often have persistent cough, fevers, and weight loss.

Valley fever occurs in approximately 25% of patients and is characterized by erythema nodosum and erythema multiforme of the upper trunk and extremities in association with diffuse joint aches or fever. More commonly, a diffuse, mild erythroderma or maculopapular rash is observed. Patients can have pleuritic chest pain and peripheral eosinophilia.

Disseminated disease occurs in less than 1% of infected patients. The most common sites for dissemination are the skin, lymph nodes, bone, and meninges, although the spleen, liver, kidney, and adrenal gland also can be involved. Occasionally, miliary coccidioidomycosis occurs, with rapid, widespread dissemination, often in concert with positive blood cultures for *C. immitis*. Patients with AIDS frequently present with miliary disease. Coccidioidomycosis in AIDS patients appears to be caused by reactivation of disease in most patients.

CNS infection occurs in approximately 16% of patients with disseminated coccidioidomycosis. Patients can present with meningeal disease without previous symptoms of primary pulmonary infection, although disease usually occurs within 6 months of the primary infection. The signs and symptoms are often subtle and nonspecific, including headache, weakness, changes in mental status (lethargy and confusion), neck stiffness, low-grade fever, weight loss, and occasionally, hydrocephalus. Space-occupying lesions are rare, and the main areas of involvement are the basilar meninges.

DIAGNOSIS

Laboratory Tests

Recovery of *C. immitis* from infected tissues or secretions for direct examination and culture provides an accurate and rapid method of diagnosis. For the safe isolation of *Coccidioides* spp., the laboratory should maintain a biological safety level 2 or 3. Direct microscopic examination and histopathologic studies of infected tissues will reveal the large, mature endosporulating spherules. Young spherules without endospores can be confused, however, with other fungi. Silver stains of body fluids or tissue biopsies are also helpful.

With chronic, persistent pneumonia, *C. immitis* often can be cultured from the sputum for a period of several years. Chest radiographs usually demonstrate apical fibronodular lesions or slowly progressive cavitation. With CNS infection, analysis of the CSF generally reveals a lymphocytic pleocytosis with elevated protein and a decreased glucose concentration. Although serum usually is positive for coccidioidal CF antibodies, the coccidioidal skin test is often negative.

Other Diagnostic Tests

Most patients develop a positive skin test within 3 weeks of the onset of symptoms. Baseline evaluation of skin test reactivity and serology is essential to assess cell-mediated immunity. Patients who develop early positive skin-test reactivity or whose coccidioidin skin-test reactivity turns from negative to positive during therapy have an improved prognosis compared with patients whose skin-test reactivity develops later or does not change during therapy. Patients with disseminated coccidioidomycosis whose skin tests are persistently negative are more likely to require prolonged therapy, and they are more likely to relapse after completion of therapy.

Antibody production can be used to follow the course of disease because most patients produce antibodies in response to infection with *C. immitis*. Early infection is characterized by the development of the IgM antibody, which peaks within 2 to 3 weeks of infection and then declines rapidly. The IgM antibody can be detected by either tube precipitin or immunodiffusion techniques.

The IgG antibody levels increase between 4 and 12 weeks after infection and decrease slowly over months to years, and IgG can be detected in many body fluids, including serum, CSF, and pleural fluid, by CF and ID techniques. Higher titers (>1:16 or 1:32) occur more frequently with severe disease. Titers can be followed serially to evaluate the efficacy of antifungal therapy.

Radiographic features tend to be quite variable; hilar adenopathy with alveolar infiltrates, tissue excavation of an infiltrate (resulting in a thin-walled cavity), or small pleural effusions are all seen commonly. With chronic persistent pneumonia, chest radiographs usually demonstrate apical fibronodular lesions or slowly progressive cavitation.[21,22]

TREATMENT

Coccidioidomycosis

GENERAL GUIDELINES

6 Therapy for coccidioidomycosis is difficult, and the results are unpredictable. Guidelines are available for treatment of this disease; however, optimal treatment for many forms of this disease still generates debate.[20] The efficacy of antifungal therapy for coccidioidomycosisis often is less certain than that for other fungal etiologies, such as blastomycosis, histoplasmosis, or cryptococcus, even when in vitro susceptibilities and the sites of infections are similar. The refractoriness of coccidioidomycosis can relate to the ability of *C. immitis* spherules to release hundreds of endospores, maximally challenging host defenses.[20,22] Fortunately, only approximately 5% of infected patients require therapy.[22]

GOALS OF THERAPY

Desired outcomes of treatment are resolution of signs and symptoms of infection, reduction of serum concentrations of anticoccidioidal antibodies, and return of function of involved organs. It would also be desirable to prevent relapse of illness on discontinuation of therapy, although current therapy is often unable to achieve this goal.

SPECIFIC AGENTS USED FOR THE TREATMENT OF COCCIDIOIDOMYCOSIS

Azole antifungals, primarily fluconazole and itraconazole, have replaced amphotericin B as initial therapy for most chronic pulmonary or disseminated infections. Amphotericin B is now usually reserved for patients with respiratory failure because of infection with Coccidioides species, those with rapidly progressive coccidioidal infections, or women during pregnancy. Therapy often ranges from many months to years in duration, and in some patients, lifelong suppressive therapy is needed to prevent relapses. Specific antifungals (and their usual dosages) for the treatment of coccidioidomycosis include intravenous amphotericin B (0.5 to 1.5 mg/kg per day), ketoconazole (400 mg/day orally), intravenous or oral fluconazole (usually 400 to 800 mg/day, although dosages as high as 1200 mg/day have been used without complications), and itraconazole (200 to 300 mg orally twice daily or three times daily, as either capsules or solution).[20,22] If itraconazole is used, measurement of serum concentrations can be helpful to ascertain whether oral bioavailability is adequate.

Amphotericin B generally is preferred as initial therapy in patients with rapidly progressive disease, whereas azoles generally are preferred in patients with subacute or chronic presentations. The lipid formulations of amphotericin B have not been studied extensively in coccidioidal infection but can offer a means of giving more drug with less toxicity. Fluconazole probably is the most frequently used medicine given its tolerability, although high relapse rates have been reported in some studies. Relapse rates with itraconazole therapy can be lower than with fluconazole.[20,22]

The usefulness of newly available antifungal agents of possible benefit for the treatment of refractory coccidioidal infections has not been adequately assessed and they are not yet FDA approved for use in this population. Case reports have suggested that voriconazole can be effective in selected patients. Caspofungin has been effective in treating experimental murine coccidioidomycosis, but in-vitro susceptibility of isolates varies widely, and there is only one report regarding its value. Posaconazole was shown to be an effective treatment in a small clinical trial and in patients with refractory infections. Its efficacy relative to other triazole antifungals is unknown.

Combination therapy with members of different classes of antifungal agents has not been evaluated in patients, and there is a hypothetical risk of antagonism. However, some clinicians feel that outcome in severe cases is improved when amphotericin B is combined with an azole antifungal. If the patient improves, the dosage of amphotericin B can be slowly decreased while the dosage of azole is maintained.[20,22]

CLINICAL CONTROVERSY

Because of the lack of prospective, controlled trials, there is continued disagreement among experts in endemic areas whether patients with coccidioidomycosis should be treated, and if so, which ones and for how long. The excellent tolerability of oral azoles has lowered the threshold for deciding to treat primary infection, and some clinicians treat all primary infections. Rationales for treating a primary self-limiting infection include the ability to lessen the morbidity associated with the acute infection and the possible ability to reduce the development of more serious complications. However, there is currently no evidence that treatment of the primary infection accomplishes either of these goals.[22]

PRIMARY RESPIRATORY INFECTION

Although most patients with symptomatic primary pulmonary disease recover without therapy, management should include follow-up visits for 1 to 2 years to document resolution of disease or to identify as early as possible evidence of pulmonary or extrapulmonary complications.

Patients with a large inoculum, severe infection, or concurrent risk factors (e.g., HIV infection, organ transplant, pregnancy, or high doses of corticosteroids) probably should be treated, particularly those with high CF titers, in whom incipient or occult dissemination is likely. Because some racial or ethnic populations have a higher risk of dissemination, some clinicians advocate their inclusion in the high-risk group. Common indicators used to judge the severity of infection include weight loss (>10%), intense night sweats persisting more than 3 weeks, infiltrates involving more than one half of one lung or portions of both lungs, prominent or persistent hilar adenopathy, CF antibody titers of greater than 1:16, failure to develop dermal sensitivity to coccidial antigens, inability to work, or symptoms that persist for more than 2 months.[20,22]

Commonly prescribed therapies include currently available oral azole antifungals at their recommended doses for courses of therapy ranging from 3 to 6 months.[20,22] In patients with diffuse pneumonia with bilateral reticulonodular or miliary infiltrates, therapy usually is initiated with amphotericin B; several weeks of therapy generally are required to produce clear evidence of improvement. Consolidation therapy with oral azoles can be considered at that time. The total duration of therapy should be at least 1 year, and in patients with underlying immunodeficiency, oral azole therapy should be continued as secondary prophylaxis. Although HIV-infected patients receiving secondary prophylaxis might be at low risk for recurrence of systemic mycosis when their CD4+ T-lymphocyte counts increase to >100 cells/microliter in response to HAART, the number of patients who have been evaluated is insufficient to warrant a recommendation to discontinue prophylaxis.

INFECTIONS OF THE PULMONARY CAVITY

Many pulmonary infections that are caused by *C. immitis* are benign in their course and do not require intervention. In the absence of controlled clinical trials, evidence of the benefit of antifungal therapy is lacking, and asymptomatic infections generally are left untreated. Symptomatic patients can benefit from oral azole therapy, although recurrence of symptoms can be seen in some patients once therapy is discontinued. Surgical resection of localized cavities provides resolution of the problem in patients in whom the risks of surgery are not too high.[20,22]

EXTRAPULMONARY (DISSEMINATED) DISEASE

Nonmeningeal Disease

Almost all patients with disease located outside the lungs should receive antifungal therapy; therapy usually is initiated with 400 mg/day of an oral azole. Amphotericin B is an alternative therapy and can be necessary in patients with worsening lesions or with disease in particularly critical locations such as the vertebral column. Approximately 50% to 75% of patients treated with amphotericin B for nonmeningeal disease achieve a sustained remission, and therapy usually is curative in patients with infections localized strictly to skin and soft tissues without extensive abscess formation or tissue damage. The efficacy of local injection into joints or the peritoneum, as well as intraarticular or intradermal administration, remains poorly studied. Amphotericin B appears to be most efficacious when cell-mediated immunity is intact (as evidenced by a positive coccidioidin or spherulin skin test or low CF antibody titer). Controlled trials that document these clinical impressions are lacking, however.[20,22]

Meningeal Disease

Fluconazole has become the drug of choice for the treatment of coccidioidal meningitis. A minimum dose of 400 mg/day orally leads to a clinical response in most patients and obviates the need for intrathecal amphotericin B. Some clinicians will initiate therapy with 800 or 1,000 mg/day, and itraconazole dosages of 400 to 600 mg/day are comparably effective. It is also clear, however, that fluconazole only leads to remission rather than cure of the infections; thus suppressive therapy must be continued for life. Ketoconazole cannot be recommended routinely for the treatment of coccidioidal meningitis because of its poor CNS penetration following oral administration. Patients who do not respond to fluconazole or itraconazole therapy are candidates for intrathecal amphotericin B therapy with or without continuation of azole therapy. The

intrathecal dose of amphotericin B ranges from 0.01 to 1.5 mg given at intervals ranging from daily to weekly. Therapy is initiated with a low dosage and is titrated upward as patient tolerance develops.[20,22]

CRYPTOCOCCOSIS

EPIDEMIOLOGY

Cryptococcosis is a noncontagious, systemic mycotic infection caused by the ubiquitous encapsulated soil yeast *Cryptococcus neoformans*, which is found in soil, particularly in pigeon droppings, although disease occurs throughout the world, even in areas where pigeons are absent. Infection is acquired by inhalation of the organism. The incidence of cryptococcosis has risen dramatically in recent years, reflecting the increased numbers of immunocompromised patients, including those with malignancies, diabetes mellitus, chronic renal failure, and organ transplants and those receiving immunosuppressive agents. The AIDS epidemic also has contributed to the increased numbers of patients; cryptococcosis is the fourth most common infectious complication of AIDS and the second most common fungal pathogen.[23]

Although *C. neoformans* produces no toxins and evokes only a minimal inflammatory response in tissue, the polysaccharide capsule appears to allow the organism to resist phagocytosis by the host. The capsular polysaccharide of *C. neoformans* appears to comprise the major virulence factor for this pathogen. Four serotypes of *C. neoformans* (A through D) have been identified; they vary in their polysaccharide content, virulence, geographic foci, and response to antifungal therapy. Serotypes A and D are commonly associated with pigeon droppings and other environmental sites and generally require shorter therapy than do infections caused by serotypes B or C, which have been found only in infected humans and animals. Serotypes B and C appear more resistant to antifungal agents in vitro. Patients with AIDS are almost always infected with serotypes A and D, even in areas endemic for serotypes B and C. There is no particular geographic area of endemic focus for *C. neoformans*.

Cell-mediated immunity appears to play a major role in host defense against infection with *C. neoformans;* 29% to 55% of patients with cryptococcal meningitis have a predisposing condition. Many patients with disseminated cryptococcosis demonstrate defects in cell-mediated immunity. The predilection of *C. neoformans* for the CNS appears to be caused by the lack of immunoglobulins and complement and the excellent growth medium afforded by CSF.[23]

Disease can remain localized in the lungs or can disseminate to other tissues, particularly the CNS, although the skin also can be affected. Hematogenous spread generally occurs in the immunocompromised host, although it also has been seen in individuals with intact immune systems. Cryptococcemia is the most common symptomatic extraneural infection associated with *C. neoformans*. Cryptococcemia can be documented in 5% to 22% of non-AIDS patients, and CNS involvement of *C. neoformans* can be found in 18% to 50% of AIDS patients. Cryptococcal disease is present in 7.5% to 10% of AIDS patients. Therefore, patients with evidence of extraneural cryptococcosis should be evaluated for CNS disease.

CLINICAL PRESENTATION OF CRYPTOCOCCOSIS[11,23,24]

Primary cryptococcosis in humans almost always occurs in the lungs, although the pulmonary focus usually produces a subclinical infection. Symptomatic infections usually are manifested by cough, rales, and shortness of breath that generally resolve spontaneously. In non-AIDS patients, the symptoms of cryptococcal meningitis are nonspecific. Headache, fever, nausea, vomiting, mental status changes, and neck stiffness generally are observed. Less common symptoms include visual disturbances (photophobia and blurred vision), papilledema, seizures, and aphasia. In AIDS patients, fever and headache are common, but meningismus and photophobia are much less common than in non-AIDS patients. Approximately 10% to 12% of AIDS patients have asymptomatic disease, similar to the rate observed in non-AIDS patients.[24]

Laboratory Tests

With cryptococcal meningitis, the CSF opening pressure generally is elevated. There is a CSF pleocytosis (usually lymphocytes), leukocytosis, a decreased glucose concentration, and an elevated CSF protein concentration. There is also a positive cryptococcal antigen (detected by LA). The test is rapid, specific, and extremely sensitive, but false-negative results can occur. False-positive tests can result from cross-reactivity with rheumatoid factor and *Trichosporon beigelli. C. neoformans* can be detected in approximately 60% of patients by India ink smear of CSF, and it can be cultured in more than 96% of patients. Occasionally, large volumes of CSF are required to confirm the diagnosis.

The CSF parameters in patients with AIDS are similar to those seen in non-AIDS patients, with the exception of a decreased inflammatory response to the pathogen, resulting in a strikingly low number of leukocytes in CSF and extraordinarily high cryptococcal antigen titers.

TREATMENT

Cryptococcosis

The choice of treatment for disease caused by *C. neoformans* depends on both the anatomic sites of involvement and the host's immune status.

NONIMMUNOCOMPROMISED PATIENTS

For asymptomatic immunocompetent hosts with isolated pulmonary disease and no evidence of CNS disease, careful observation can be warranted; in the case of symptomatic infection, fluconazole or amphotericin B is warranted (Table 130–6). In individuals with non-CNS cryptococcemia, a positive serum cryptococcal antigen titer (>1:8), cutaneous infection, a positive urine culture, or prostatic disease, the clinician must decide whether to follow the regimen for isolated pulmonary disease or the more aggressive regimen for patients with CNS (disseminated) disease.[15]

❼ Prior to the introduction of amphotericin B, cryptococcal meningitis was an almost uniformly fatal disease; approximately 86% of patients died within 1 year. The use of large (1 to 1.5 mg/kg) daily doses of amphotericin B resulted in cure rates of approximately 64%. When amphotericin B is combined with flucytosine, a smaller dose of amphotericin B can be employed because of the in vitro and in vivo synergy between the two antifungal agents. Resistance develops to flucytosine in up to 30% of patients treated with flucytosine alone, limiting its usefulness as monotherapy.[24,25] Combination therapy with amphotericin B and flucytosine will sterilize the CSF within 2 weeks of treatment in 60% to 90% of patients, and most immunocompetent patients will be treated successfully with 6 weeks of combination therapy.[23] However, because of the need for prolonged IV therapy and the potential for renal and hematologic toxicity with this regimen, alternative regimens have been advocated. Despite a lack of clinically controlled trials in this population, amphotericin B induction therapy for 2 weeks, followed by consolidation therapy with fluconazole for an additional 8 to 10 weeks, is

TABLE 130-6 Therapy of Cryptococcosis[a,b]

Type of Disease and Common Clinical Manifestations	Therapy/Comments
Nonimmunocompromised host	Comparative trials for amphotericin B[c] versus azoles not available
Isolated pulmonary disease (without evidence of CNS infection)	*Asymptomatic disease:* Drug therapy generally not required; observe carefully or fluconazole 400 mg orally daily × 3–6 months *Mild to moderate symptoms:* Fluconazole 200–400 mg orally daily × 3–6 months *Severe disease or inability to take azoles:* Amphotericin B 0.4–0.7 mg/kg/day (total dose of 1–2 g)
Cryptococcemia with positive serum antigen titer (>1:8), cutaneous infection, a positive urine culture, or prostatic disease	Clinician must decide whether to follow the pulmonary therapeutic regimen or the CNS (disseminated) regimen
Recurrent or progressive disease not responsive to amphotericin B; Isolated pulmonary disease (without evidence of CNS infection)	Amphotericin B[d] IV 0.5–0.75 mg/kg/day ± IT amphotericin B 0.5 mg 2–3 times weekly *Mild to moderate symptoms or asymptomatic with a positive pulmonary specimen:* Fluconazole 200–400 mg orally daily × lifelong *or* Itraconazole 200–400 mg orally daily × lifelong *or* Fluconazole 400 mg orally daily + flucytosine 100–150 mg/kg/day orally × 10 weeks *Severe disease:* Amphotericin B until symptoms are controlled, followed by fluconazole
CNS disease	
Acute (induction/consolidation therapy) (follow all regimens with suppressive therapy)	Amphotericin B[d] IV 0.7–1 mg/kg/day + flucytosine 100 mg/kg/day orally × ≤ 2 weeks, then fluconazole 400 mg orally daily × ≤ 8 weeks[e] *or* Amphotericin B[d] IV 0.7–1 mg/kg/day + flucytosine 100 mg/kg/day orally × 6–10 weeks[e] *or* Amphotericin B[d] IV 0.7–1 mg/kg/day × 6–10 weeks[e] *or* Fluconazole 400–800 mg orally daily × 10–12 weeks *or* Itraconazole 400–800 mg orally daily × 10–12 weeks *or* Fluconazole 400–800 mg orally daily + flucytosine 100–150 mg/kg/day orally × 6 weeks[e] *or* Lipid formulation of amphotericin B IV 3–6 mg/kg/day × 6–10 weeks *Note:* Induction therapy with azoles alone is discouraged.
CNS disease	Amphotericin B[d] IV 0.7–1 mg/kg/day + flucytosine 100 mg/kg/day orally × 2 weeks, followed by fluconazole 400 mg orally daily for a minimum of 10 weeks (in patients intolerant to fluconazole, substitute itraconazole 200–400 mg orally daily) *or* Amphotericin B[d] IV 0.7–1 mg/kg/day + 5-flucytosine 100 mg/kg/day orally × 6–10 weeks *or* Amphotericin B[d] IV 0.7–1 mg/kg/day × 10 weeks *Refractory disease:* Intrathecal or intraventricular amphotericin B
Immunocompromised patients	
Non-CNS pulmonary and extrapulmonary disease	Same as nonimmunocompromised patients with CNS disease
CNS disease	Amphotericin B[d] IV 0.7–1 mg/kg/day × 2 weeks, followed by fluconazole 400–800 mg orally daily 8–10 weeks, followed by fluconazole 200 mg orally daily × 6–12 months (in patients intolerant to fluconazole, substitute itraconazole 200–400 mg orally daily) *Refractory disease:* Intrathecal or intraventricular amphotericin B
HIV-infected patients	
Suppressive/maintenance therapy	Fluconazole 200–400 mg orally daily × lifelong *or* Itraconazole 200 mg orally twice daily × lifelong *or* Amphotericin B IV 1 mg/kg 1–3 times weekly × lifelong

HIV, human immunodeficiency virus; IT, intrathecal.
[a]When more than one therapy is listed, they are listed in order of preference.
[b]See text for definitions of induction, consolidation, suppressive/maintenance therapy, and prophylactic therapy.
[c]Deoxycholate amphotericin B.
[d]In patients with significant renal disease, lipid formulations of amphotericin B can be substituted for deoxycholate amphotericin B during the induction.
[e]Or until cerebrospinal fluid (CSF) cultures are negative
Data from Bennett et al.,[23] Francis and Walsh,[24] Powderly et al.,[25] Saag et al.,[26] and van der Horst et al.[27]

frequently recommended based on data extrapolated from studies conducted in HIV-infected patients. Suppressive therapy with fluconazole 200 mg/day for 6 to 12 months after the completion of induction and consolidation therapy is optional.[15,25–27]

Pilot studies evaluating combination therapy with fluconazole plus flucytosine as initial therapy yielded unsatisfactory results, and this approach is discouraged even in "low-risk" patients. Ketoconazole has been used successfully in the treatment of cutaneous cryptococcosis, but it is not useful in the treatment of CNS disease, probably because of its poor penetration into the CNS.[15]

Despite low CSF concentrations of amphotericin B (2% to 3% of those observed in plasma), the use of intrathecal amphotericin B is not recommended for the treatment of cryptococcal meningitis except in very ill patients or in patients with recurrent or

progressive disease despite aggressive therapy with IV amphotericin B. The dosage of amphotericin B employed is usually 0.5 mg administered through the lumbar, cisternal, or intraventricular (through an Ommaya reservoir) route 2 or 3 times weekly. Side effects of intrathecal amphotericin B include arachnoiditis and paresthesias. Intrathecal amphotericin B therapy should be administered in combination with IV amphotericin B.[27]

IMMUNOCOMPROMISED PATIENTS

Immunocompromised hosts with isolated pulmonary and extrapulmonary disease without CNS disease should be treated similarly to nonimmunocompromised patients with CNS disease. Immunocompromised patients with CNS infection require more prolonged therapy; treatment regimens are based on those used in the HIV-infected population and follow induction and consolidation therapy with 6 to 12 months of suppressive therapy with fluconazole.[15]

HIV-Infected Patients

There are no controlled clinical trials evaluating the therapy of isolated pulmonary infection; thus the specific treatment of choice is unclear. However, because these patients are at high risk for disseminated infection, antifungal therapy is warranted in all patients. Lifelong therapy with fluconazole is recommended; in patients for whom fluconazole is not an option, itraconazole can be used.

Fluconazole is beneficial for both acute and chronic maintenance therapy for cryptococcal meningitis. Amphotericin B 0.4 to 0.5 mg/kg IV daily was compared with oral fluconazole 200 mg/day. Although the overall 10-week mortality was the same in both groups, the time until the CSF culture became negative was longer, and there were more deaths in the first 2 weeks of therapy in the fluconazole group.[26] In later trials,[27] amphotericin B 0.7 mg/kg IV daily for 2 weeks (with or without oral flucytosine 100 mg/kg per day), followed by consolidation therapy with either itraconazole 400 mg/day orally or fluconazole 400 mg/day orally, led to markedly improved outcomes in comparison with earlier regimens. This study confirmed the benefit of early high-dose (0.7 mg/kg per day) amphotericin B use, the usefulness of flucytosine added to amphotericin B for induction therapy, and the slight superiority of fluconazole over itraconazole for consolidation therapy.

Amphotericin B combined with flucytosine is the initial treatment of choice. In patients who cannot tolerate flucytosine, amphotericin B alone is an acceptable alternative. After the initially successful 2-week induction period, consolidation therapy with fluconazole can be administered for 8 weeks or until CSF cultures are negative. In patients in whom fluconazole cannot be given, itraconazole is an acceptable, albeit less effective, alternative. Combination therapy with fluconazole plus flucytosine is effective; however, it is recommended as an alternative to the preceding therapies because of its potential for toxicity. Lipid formulations of amphotericin B are effective, but the optimal dosage is unknown.[15]

In HIV-infected patients, mortality is highly associated with elevated intracranial pressure (CSF opening pressure >250 mm). At the initiation of antifungal therapy, lumbar drainage should remove enough CSF to reduce the opening pressure by 50%. Patients initially should undergo daily lumbar punctures to maintain CSF opening pressure in the normal range. When the CSF pressure is normal for several days, the procedure can be suspended. Adjunctive steroid treatment is not recommended because therapy has resulted in mixed results and its impact on outcome is unclear. Similarly, neither mannitol nor acetazolamide therapy provides any clear benefit in the management of elevated intracranial pressure.[15]

Suppressive (Maintenance) Therapy for Cryptococcal Meningitis in the HIV-Infected Patient

Relapse of *C. neoformans* meningitis occurs in approximately 50% of AIDS patients after completion of primary therapy. Persistence of asymptomatic urinary *C. neoformans* has been documented in a high percentage of AIDS patients despite seemingly adequate courses of therapy for primary meningeal disease. The prostate appears to act as a sequestered reservoir of infection in these patients, resulting in systemic relapse. Fluconazole is recommended for chronic suppressive therapy of cryptococcal meningitis in AIDS patients. The AIDS Clinical Trials Group's (ACTG) 026 study demonstrated that oral fluconazole 200 mg/day was superior to IV administration of amphotericin B 1 mg/kg weekly in preventing relapse. In addition, the fluconazole-treated group showed a lower incidence of adverse drug reactions and bacterial infections.[27] Randomized comparative trials also demonstrated the superiority of fluconazole versus itraconazole as maintenance therapy. Thus itraconazole should be reserved for patients intolerant to fluconazole. Ketoconazole is not effective as maintenance therapy.

Although the numbers of patients who have been evaluated remain limited and recurrences can occur, patients are at low risk for recurrence of cryptococcosis when they have successfully completed a course of initial therapy for cryptococcosis, remain asymptomatic with regard to signs and symptoms of cryptococcosis, and have a sustained increase (e.g., >6 months) in their CD4+ T-lymphocyte counts to >100 to 200 cells/microliter and an HIV viral load of fewer than 50 copies/mL.[15,25–28]

EVALUATION OF THERAPEUTIC OUTCOMES

Once the CNS is involved, the usual course is weeks to months of progressive deterioration, with 80% of untreated patients dying within the first year. The prognosis of cryptococcal meningitis depends largely on the underlying predisposing factors of the host. Although cryptococcal antigen is positive in 90% of patients with cryptococcal meningitis, fewer than one half of the patients with cryptococcal meningitis develop antibody to capsular polysaccharide. Those who produce antibody have a slightly improved prognosis. In contrast, the presence of headache is a favorable symptom, presumably because it leads to an earlier diagnosis. A favorable outcome is also associated with a normal mental status on diagnosis and a CSF white blood cell (WBC) count of less than 20 cells/mm^3. A poor outcome is predicted, however, by the presence of one or more underlying diseases (including hematopoietic disorders and AIDS), corticosteroid or immunosuppressive therapy, pretreatment serum cryptococcal antigen titers of 1:32, and posttherapy serum antigen titers of 1:8. In non-AIDS patients, the cryptococcal antigen titer can be followed during therapy to assess response to antifungal therapy. In AIDS patients, decreasing titers are not necessarily predictive of success, and titers rarely become negative at the completion of therapy.

CANDIDA INFECTIONS

Candida species are yeasts that exist primarily as small (4 to 6 microns), unicellular, thin-walled, ovoid cells that reproduce by budding. On agar medium, they form smooth, white, creamy colonies resembling staphylococci. Although there are more than 150 species of *Candida*, eight species—*C. albicans, C. tropicalis, Candida parapsilosis, C. krusei, Candida stellatoidea, C. guilliermondii, C. lusitaniae*, and *C. glabrata*—are regarded as clinically

important pathogens in human disease.[13] Yeast forms, hyphae, and pseudohyphae can be found in clinical specimens.

PATHOPHYSIOLOGY

8 *C. albicans* is a normal commensal of the skin, female genital tract, and entire GI tract of humans. Therefore, the mere presence of hyphae or pseudohyphae in a clinical specimen is insufficient for the diagnosis of invasive disease. The majority of infections with *C. albicans* are acquired endogenously, although human-to-human transmission also can occur. Oral candidiasis in the newborn probably is acquired during passage through the birth canal, and balanitis in the uncircumcised male can be acquired through contact with a female with vaginal candidiasis. Although the term *fungemia* refers to the presence of fungi in the blood, the most commonly isolated organism is *C. albicans*. Candidiasis can cause mucocutaneous or systemic infection, including endocarditis, peritonitis, arthritis, and infection of the CNS. (Mucocutaneous infections caused by *Candida* are discussed in further detail in Chap. 129.)

The role of an intact integument is crucial in the prevention of mucocutaneous or hematogenous candidiasis. After *Candida* invades the dermis or enters the bloodstream, polymorphonuclear (PMN) leukocytes play a major role in the defense of the patient because PMN leukocytes are capable of damaging pseudohyphae and can phagocytize and kill blastoconidia. In addition to neutrophils, lymphocytes, monocytes, macrophages, complement, and eosinophils play a role in the prevention of infection. Adherence of *C. albicans* is important in the pathogenesis of oral candidiasis and subsequent colonization of the GI tract. Because evidence suggests that the GI tract is often the portal of entry for *Candida* in disseminated disease, factors that alter the adherence of *Candida* are crucial in the development of local and systemic infection. *Candida tropicalis* adheres to intravascular catheters at a higher rate than *C. albicans*, a factor that may help to account for the increased incidence of systemic infections caused by this pathogen.

HEMATOGENOUS CANDIDIASIS

EPIDEMIOLOGY

The incidence of fungal infections caused by *Candida* species has increased substantially in the past three decades, and *Candida* infections currently constitute a significant cause of morbidity and mortality among severely ill patients. *Candida* species now constitute the fourth most common cause of bloodstream infections (BSIs) for patients hospitalized in intensive care units (ICUs) in the United States, following coagulase-negative staphylococci, *Staphylococcus aureus*, and enterococci. The Centers for Disease Control and Prevention's (CDC) National Nosocomial Infection Survey implicated fungi as the cause of 8% of nosocomial infections. Although *C. albicans* accounted for approximately 50% of *Candida* species, non-*albicans* species of *Candida*, including *C. glabrata, C. tropicalis, C. krusei*, and *C. parapsilosis*, are increasingly frequent causes of invasive candidal infections.[29–31] *Candida lusitaniae* infections are a cause of breakthrough fungemia in cancer patients; *C. parapsilosis* has emerged as the second most common pathogen, following *C. albicans*, in neonatal ICU patients, where it is often associated with central lines and parenteral nutrition, and fungemias in patients outside the United States, in particular in South America. Fungemia caused by *C. glabrata* is observed more commonly in adults older than 65 years of age.[29,32] The change in species is of concern clinically because certain pathogens, such as *C. krusei* and *C. glabrata*, are intrinsically more resistant to commonly used triazole drugs (see Table 130–1).

PATHOPHYSIOLOGY

Candida generally is acquired via the GI tract, although organisms also can enter the bloodstream via indwelling IV catheters. Immunosuppressed patients, including those with lymphoreticular or hematologic malignancies, diabetes, and immunodeficiency diseases and those receiving immunosuppressive therapy with high-dose corticosteroids, immunosuppressants, antineoplastic agents, or broad-spectrum antimicrobial agents, are at high risk for invasive fungal infections. However, a number of prospective, randomized, controlled trials have validated the efficacy of antifungal prophylaxis and the use of antifungal agents for the treatment of persistently febrile patients with neutropenia who do not respond to antibiotics, and in the prophylaxis of patients undergoing hematopoietic stem cell transplantation (HSCT), in particular in HSCT patients with graft-versus-host disease (GVHD).[33] These efforts have resulted in a reduction in the frequency of bloodstream infections caused by *Candida* species and systemic candidiasis in patients with neutropenia. In fact, most bloodstream infections caused by *Candida* species now occur in patients who have been hospitalized in ICUs, especially adult and neonatal ICUs. Retrospective studies have identified a number of risk factors for candidal bloodstream infections in ICU patients, most of which have been verified in multiple studies, although some remain controversial[34] (Table 130–7). Major risk factors include the use of central venous catheters, total parenteral nutrition, receipt of multiple antibiotics, extensive surgery and burns, renal failure and hemodialysis, mechanical ventilation, and prior fungal colonization. Patients who have undergone surgery (particularly surgery of the GI tract) are increasingly susceptible to disseminated candidal infections.[34,35]

CLINICAL PRESENTATION OF HEMATOGENOUS CANDIDIASIS[11,13]

Dissemination of *C. albicans* can result in infection in single or multiple organs, particularly the kidney, brain, myocardium, skin, eye, bone, and joints. In most patients, multiple micro- and macroabscesses are formed. Infection of the liver and spleen is becoming recognized as a particularly common and difficult-to-treat site of infection that characteristically occurs in patients undergoing chemotherapy for acute leukemia or lymphoma.

Diagnosis

Signs and Symptoms Several distinct presentations of disseminated *C. albicans* have been recognized:[10]

1. Patients present with the acute onset of fever, tachycardia, tachypnea, and occasionally, chills or hypotension. The clinical presentation generally is indistinguishable from that seen with sepsis of bacterial origin.
2. Patients develop intermittent fevers and are ill only when febrile.
3. Patients manifest progressive deterioration of their conditions with or without fever.
4. Hepatosplenic candidiasis often is manifested only as fever while the patient remains neutropenic (<1,000 WBCs/mm^3).

Laboratory Tests Although a variety of serologic tests have been proposed for the detection of *Candida* protein antigens, serum antibodies to *Candida*, and antibodies to cell wall components such as mannan, no test has demonstrated reliable accuracy in the clinical setting for the diagnosis of disseminated infection with *Candida*. Only 25% to 45% of neutropenic patients with disseminated candidiasis at autopsy had a positive blood culture with *C. albicans*

TABLE 130-7 Risk Factors for Invasive Candidiasis

Colonization
Corrected colonization index (CCI) ≥ 0.4[a]
Colonization index (CI) ≥ 0.8[a]
Candida spp. cultured from sites other than blood
Candiduria
Antibiotic use
Number of antibiotics prior to infection (per additional antibiotics)
Use of 2 or more antibiotics
Use of broad spectrum antibiotics in previous 10 days
Surgery
Surgery on ICU admission
Gastro-abdominal surgery
Abdominal drainage
Elective surgery
Cardiopulmonary bypass time > 120min
Hickman catheter
Foreign devices
Central venous catheter
Triple lumen catheter in patients who have undergone surgery
Bladder catheter
Renal failure and dialysis
Prior hemodialysis
Hemofiltration procedures
Increased serum creatinine[b]
New onset hemodialysis within 3 days of admission to ICU
Acute renal failure
Underlying disease/baseline characteristics
Total parenteral nutrition
Diabetes mellitus
Apache II (per point)
Signs of severe sepsis
Diarrhea at any time
Mechanical ventilation ≥ 10 days
Hospital acquired bacterial infection
Bacterial peritonitis by ICU day 11
Gastrointestinal disease
ICU length of stay
Transferred from other hospital
Use of corticosteroids
Profound neutropenia (ANC < 100/mm³)

[a]CI = the ratio of number of nonblood distinct body sites (dbs) heavily colonized with identical strains to total number of dbs; CCI = the product of the CI and the ratio of the number of dbs showing heavy growth (≥10^5 CFU/mL) to the total of dbs growing *Candida* spp.
[b]Serum creatinine >1.2 mg/dl in females, >1.6 mg/dl in males
Data from Lam et al.[34] and Wey et al.[35]

prior to death. The interpretation of positive surveillance cultures of the skin, mouth, sputum, feces, or urine is hampered by their occurrence as commensal pathogens and in distinguishing colonization from invasive disease.

Until recently, a rapid presumptive identification of *C. albicans* could be made by incubation of the organism in serum; formation of a germ tube (the beginning of hyphae, which arise as perpendicular extensions from the yeast cell, with no constriction at their point of origin) within 1 to 2 hours offered a positive identification of *C. albicans*. Unfortunately, *C. dubliniensis*, a new species of *Candida* that was identified recently as an important cause of mucosal colonization and infection in HIV-infected individuals, also can produce a germ tube. A negative germ tube test does not rule out the possibility of *C. albicans*, but further biochemical tests must be performed to differentiate between other non-*albicans* species.[36]

In patients with hepatosplenic candidiasis, as the WBC count increases to >1,000 cells/mm³, imaging studies can detect the presence of abscess or microabscesses in the liver and spleen, often found with acute suppurative and granulomatous reactions.

A new peptide nucleic acid (PNA) fluorescence in situ hybridization (FISH) method uses fluorescein-labeled PNA probes that target *C. albicans* 26S rRNA for the identification of *C. albicans* directly from blood culture bottles that test positive, and in which yeasts observed by Gram staining have been developed. The probe is added to smears made directly from the contents of blood culture bottles and is hybridized for 90 minutes, and the smears are subsequently examined by fluorescence microscopy. The test has excellent sensitivity (99% to 100%) and specificity (100%) in the direct identification of *C. albicans* from blood cultures.[14]

TREATMENT

Hematogenous Candidiasis

Fraser and colleagues[34] documented the high rate of mortality in nonneutropenic patients with fungal blood cultures. Mortality was highest in patients with sustained positive blood cultures, those who did not receive antifungal therapy, and those infected with non-*albicans* strains of *Candida*. This study clearly documented the importance of early recognition and treatment of positive fungal blood cultures. Prompt initiation of therapy is important. Delays in empiric antifungal treatment greater than 12 hours after obtaining a positive blood sample are associated with greater hospital mortality.[37,38,39] Despite increased awareness of the importance of treating patients with positive blood cultures, mortality associated with candidemia remains high.[40]

Treatment of candidiasis should be guided by knowledge of the infecting species; the clinical status of the patient; when available, the antifungal susceptibility of the infecting isolate; and whether the patient has received antifungal therapy previously (Table 130–8). Therapy should be continued for 2 weeks after the last positive blood culture and resolution of signs and symptoms of infection. All patients should undergo an ophthalmologic examination to exclude the possibility of candidal endophthalmitis.[7] Amphotericin B can be switched to fluconazole (intravenous or oral) for the completion of therapy. Susceptibility testing of the infecting isolate is a useful adjunct to species identification during selection of a therapeutic approach because it can be used to identify isolates that are unlikely to respond to fluconazole or amphotericin B. However, this is not currently available at most institutions.

NONIMMUNOCOMPROMISED PATIENT

Prophylaxis

In ICUs, the use of fluconazole for prophylaxis or empirical therapy has increased exponentially in the past decade. However, studies that demonstrated benefit in the prevention of invasive candidal bloodstream infections did so either by using highly selective criteria or by studying patients in an unusually high-risk ICU setting, and the role of antifungal prophylaxis in the surgical ICU remains extremely controversial. Rex and colleagues[7] have suggested that for a study to demonstrate efficacy in clinical trials, the baseline rate of invasive candidiasis must be >10%, and that prophylaxis must result in > fourfold reduction of disease. Although ICU-specific, a >10% rate of invasive candidiasis is generally found only in the setting of high-risk transplant patients (e.g., patients undergoing liver transplantation), or in patients with one or more of the following risk factors by day 3 of their ICU stay: new onset dialysis, receipt of broad-spectrum antibiotics, the presence of diabetes, and in patients receiving parenteral nutrition.[41–43]

TABLE 130-8 Therapy of Invasive Candidiasis[7,34]

Type of Disease and Common Clinical Manifestations	Therapy/Comments
Prophylaxis of candidemia	
Nonneutropenic patients[a]	Not recommended except for severely ill/high-risk patients in whom fluconazole IV/PO 400 mg daily should be used (see text)
Neutropenic patients[a]	The optimal duration of therapy is unclear but at a minimum should include the period at risk for neutropenia: Fluconazole IV/PO 400 mg daily *or* itraconazole solution 2.5 mg/kg every 12 hours PO *or* micafungin 50 mg (1 mg/kg in patients under 50 kg) intravenously daily
Solid-organ transplantation, liver transplantation	*Patients with two or more key risk factors*[b]*:* Amphotericin B IV 10–20 mg daily *or* liposomal amphotericin B (AmBisome) 1 mg/kg/day *or* fluconazole 400 mg orally daily
Empirical antifungal therapy (unknown *Candida* species)	
Suspected disseminated candidiasis in febrile nonneutropenic patients	None recommended; data are lacking defining subsets of patients who are appropriate for therapy (see text)
Febrile neutropenic patients with prolonged fever despite 4–6 days of empirical antibacterial therapy	*Treatment duration:* Until resolution of neutropenia An echinocandin[d] is a reasonable alternative; Voriconazole can be used in selected situations (see text)
Less critically ill patients with no recent azole exposure	An echinocandin[d] or fluconazole (loading dose of 800 mg [12 mg/kg], then 400 mg [6 mg/kg] daily)
Additional mold coverage is desired	Voriconazole
Empirical therapy of candidemia and acute hematogenously disseminated candidiasis	
Nonimmunocompromised host[c]	*Treatment duration:* 2 weeks after the last positive blood culture and resolution of signs and symptoms of infection *Remove existing central venous catheters when feasible plus* *fluconazole (loading dose of 800 mg [12 mg/kg], then 400 mg [6 mg/kg] daily) or an echinocandin*[d]
Patients with recent azole exposure, moderately severe or severe illness, or who are at high risk of infection due to *C. glabrata* or *C. krusei*	An echinocandin[d] Transition from an echinocandin to fluconazole is recommended for patients who are clinically stable and have isolates (eg, *C. albicans*) likely to be susceptible to fluconazole
Patients who are less critically ill and who have had no recent azole exposure	Fluconazole
Therapy of specific pathogens	
Candida albicans, Candida tropicalis, Candida parapsilosis	Fluconazole IV/PO 6 mg/kg/day *or* an echinocandin[d] *or* amphotericin B IV 0.7 mg/kg/day plus fluconazole IV/PO 800 mg/day; Amphotericin B deoxycholate 0.5–1.0 mg/kg daily or a lipid formulation of amphotericin B (3–5 mg/kg daily) are alternatives in patients who are intolerant to other antifungals; Transition from Amphotericin B deoxycholate or a lipid formulation of amphotericin B to fluconazole is recommended in patients who are clinically stable and whose isolates are likely to be susceptible to fluconazole (eg *C. albicans*); Voriconazole (400 mg [6 mg/kg] twice daily x 2 doses then 200 mg [3mg/kg] twice daily thereafter is efficacious, but offers little advantage over fluconazole; It may be utilized as stepdown oral therapy for selected cases of candidiasis due to *C. krusei* or voriconazole-susceptible *C. glabrata* *Patients intolerant or refractory to other therapy*[e]: Amphotericin B lipid complex IV 5 mg/kg/day Liposomal amphotericin B IV 3–5 mg/kg/day Amphotericin B colloid dispersion IV 2–6 mg/kg/day
Candida krusei	Amphotericin B IV ≤1 mg/kg/day *or* an echinocandin[d]
Candida lusitaniae	Fluconazole IV/PO 6 mg/kg/day
Candida glabrata	An echinocandin[d](Transition to fluconazole or voriconazole therapy is not recommended without confirmation of isolate susceptibility)
Neutropenic host[f]	*Treatment duration:* Until resolution of neutropenia *Remove existing central venous catheters when feasible, plus:* Amphotericin B IV 0.7–1 mg/kg/day (total dosages 0.5–1 g) *or Patients failing therapy with traditional amphotericin B:* Lipid formulation of amphotericin B IV 3–5 mg/kg/day
Chronic disseminated candidiasis (hepatosplenic candidiasis)	*Treatment duration:* Until calcification or resolution of lesions *Stable patients:* Fluconazole IV/PO 6 mg/kg/day *Acutely ill or refractory patients:* Amphotericin B IV 0.6–0.7 mg/kg/day
Urinary candidiasis	*Asymptomatic disease:* Generally no therapy is required *Symptomatic or high-risk patients*[g]: Removal of urinary tract instruments, stents, and Foley catheters, +7–14 days therapy with fluconazole 200 mg orally daily *or* amphotericin B IV 0.3–1 mg/kg/day

PO, orally.

[a]Patients at significant risk for invasive candidiasis include those receiving standard chemotherapy for acute myelogenous leukemia, allogeneic bone marrow transplants, or high-risk autologous bone marrow transplants. However, among these populations, chemotherapy or bone marrow transplant protocols do not all produce equivalent risk, and local experience should be used to determine the relevance of prophylaxis.

[b]Risk factors include retransplantation, creatinine of more than 2 mg/dL, choledochojejunostomy, intraoperative use of 40 units or more of blood products, and fungal colonization detected within the first 3 days after transplantation.

[c]Therapy is generally the same for acquired immunodeficiency syndrome (AIDS)/non-AIDS patients except where indicated and should continued for 2 weeks after the last positive blood culture and resolution of signs and symptoms of infection. All patients should receive an ophthalmologic examination. Amphotericin B can be switched to fluconazole (intravenous or oral) for the completion of therapy. Susceptibility testing of the infecting isolate is a useful adjunct to species identification during selection of a therapeutic approach because it can be used to identify isolates that are unlikely to respond to fluconazole or amphotericin B. However, this is not currently available at most institutions.

[d]Echinocandin = caspofungin 70 mg loading dose, then 50 mg IV daily maintenance dose, or micafungin 100 mg daily, or anidulafungin 200 mg loading dose, then 100 mg daily maintenance dose.

[e]Often defined as failure of ≥500 mg amphotericin B, initial renal insufficiency (creatinine ≥2.5 mg/dL or creatinine clearance <25 mL/min), a significant increase in creatinine (to 2.5 mg/dL for adults or 1.5 mg/dL for children), or severe acute administration-related toxicity.

[f]Patients who are neutropenic at the time of developing candidemia should receive a recombinant cytokine (granulocyte colony-stimulating factor or granulocyte-monocyte colony-stimulating factor) that accelerates recovery from neutropenia.

[g]Patients at high risk for dissemination include neutropenic patients, low-birth-weight infants, patients with renal allografts, and patients who will undergo urologic manipulation.

Data from NCCLS,[5] Pappas et al.[7,40]

TABLE 130-9 Treatment of Candidemia in the Nonneutropenic Host

Year Published	Study Drugs and Dosages	Study Design	Results and Comments
1994	Fluconazole vs. amphotericin B	Randomized, non-blinded, multicenter	Similar outcomes but higher rate of nephrotoxicity in the amphotericin B group
2002	Caspofungin (70 mg IV × 1 loading dose; then 50 mg IV daily) vs. amphotericin B (0.6–0.7 mg/kg/day IV) each antifungal agent was changed to fluconazole after ≥10 days to complete therapy	Randomized, multicenter	Successful outcome was achieved in 73.9% and 61.7% of patients receiving caspofungin and amphotericin B, respectively, but there was a higher rate of nephrotoxicity in the amphotericin B group
2003	Fluconazole 800 mg/day + placebo vs. fluconazole 800 mg/d + amphotericin B 0.7 mg/kg/day	Randomized, blinded, multicenter	The study was confounded by differences in the severity of illness of the two study populations (the fluconazole group had more severe illness). The regimens were comparable and noted a trend toward better response (based principally on more effective bloodstream clearance) in the group receiving combination therapy
2005	Voriconazole (6 mg/kg IV every 12 hours on day 1; 3 mg/kg every 12 hours IV on days 2 and 3; then 200 mg PO every 12 hours) vs. amphotericin B (≤0.7 mg/kg/day) followed by fluconazole (≥400 mg PO/ IV daily)	Randomized, non-blinded, multicenter	Voriconazole was as effective as the regimen of amphotericin B followed by fluconazole in the clearing of blood cultures; Treatment discontinuations cased by all-cause adverse events were more frequent in the voriconazole group, although most discontinuations were caused by non–drug-related events, and there were significantly fewer serious adverse events and cases of renal toxicity than in the amphotericin B/fluconazole group
2005	Anidulafungin (200 mg loading dose × 1, then 100 mg/day) vs. IV fluconazole (800 mg loading dose × 1, then 400 mg/day)	Randomized, double-blind	A statistically significantly greater response was observed with anidulafungin in the microbiologic intent-to-treat arm at the end of IV therapy, and at the 2-week and 6-week follow-ups in patients with APACHE II scores of >20; Survival was improved with anidulafungin
2005	Micafungin (100 mg/day IV) vs. liposomal amphotericin B (3 mg/kg/day) × 2–4 weeks	Randomized, double-blind	Micafungin treatment was considered effective (clinical plus mycological response) in 89.6% of patients (181:202), compared to 89.5% (170:190) in the amphotericin B group. The amphotericin B group had a significantly higher incidence of side effects, including infusion-related reactions and increases in serum creatinine.
2006	Caspofungin (70 mg IV × 1 loading dose; then 50 mg IV daily) vs. micafungin 100 mg/day vs. micafungin 150 mg/day	Randomized, double-blind	Micafungin was found noninferior to caspofungin; Higher dosages of micafungin (150 mg/day vs. 100 mg/day) were not more efficacious; The safety profiles for the three treatments were similar

APACHE, Acute Physiology and Chronic Health Evaluation; PO, orally.

Empirical Therapy

Few data are available for assessing the role of fluconazole as empirical therapy for suspected fungemia or for isolates other than *C. albicans*. Because fluconazole has poor activity against *Aspergillus* species and some non-*albicans* strains of *Candida*, many clinicians advocate amphotericin B as the therapy of choice in patients with suspected fungemia. If therapy is given, its use should be limited to patients with (a) *Candida* colonization at multiple sites, (b) multiple other risk factors, and (c) the absence of any other uncorrected causes of fever.[7]

Specific Therapy

Several large randomized studies in nonneutropenic patients have demonstrated that azoles (fluconazole or voriconazole) and deoxycholate amphotericin B are similarly effective; however, fewer adverse effects are observed with azole therapy (Table 130–9). Similarly, echinocandins are at least as effective as amphotericin B or fluconazole in (mainly nonneutropenic) adult patients with candidemia with fewer drug-related adverse events. Although the use of combination therapy (high-dose fluconazole plus amphotericin B) was demonstrated recently to be superior to treatment with fluconazole alone, it was associated with a higher rate of nephrotoxicity, and the routine use of combination therapy in this patient population is not yet recommended. Alternatives to fluconazole should be considered when patients have a history of recent exposure to fluconazole or other azoles, when a broader spectrum is desirable (e.g., persistently neutropenic patient), when non-*albicans* species are isolated during or immediately following azole therapy, and in unstable or severely immunocompromised patients.[44–50]

Neonates with disseminated candidiasis usually are treated with amphotericin B because of its low toxicity in this patient population and because of the lack of experience with other agents in this population; however, micafungin or caspofungin may offer safe, effective alternatives.[7,12,40] Treatment should continue until 2 weeks following the last positive blood culture and resolution of signs and symptoms of infection.

C. krusei infections should be treated with large doses of amphotericin B (≥1 mg/kg per day) or with caspofungin (70-mg IV loading dose, followed by 50 mg/day IV).[7] *C. tropicalis*, and *C. parapsilosis* can be treated with either amphotericin B at 0.6 mg/kg per day or fluconazole at 6 mg/kg per day. Amphotericin B resistance remains relatively rare despite more than 45 years of clinical use, although it has been reported in *C. lusitaniae* (now *Clavispora lusitaniae*) and *C. guilliermondii*. *Candida rugosa* often is considered to be "polyene tolerant," and these isolates are believed to be selected owing to the wide use of amphotericin B.

Among the lipid-associated formulations of amphotericin B, only liposomal amphotericin B (AmBisome) and amphotericin B lipid complex (Abelcet) have been approved for use in proven cases of candidiasis; however, patients with invasive candidiasis also have been treated successfully with amphotericin B colloid dispersion (Amphotec or Amphocil). The lipid-associated formulations are less toxic but as effective as amphotericin B deoxycholate.

IMMUNOCOMPROMISED PATIENTS

In immunocompromised patients, the presence of candidemia is associated with evidence of disseminated disease in more than 70% of patients and with a 70% to 80% fatality rate. Therapy should include removal of the catheter and administration of systemic antifungal therapy.[7] The optimal agent, dose, and duration of therapy are unclear, and patients must be monitored carefully with serial blood cultures and careful physical examinations, particularly of the retina. Patients who are neutropenic at the time of developing candidemia should receive a recombinant cytokine (granulocyte colony-stimulating factor or granulocyte-monocyte colony-stimulating factor) that accelerates recovery from neutropenia.[7]

Prophylaxis

Recognition of the role of the GI tract in invasive *Candida* infections has led to efforts to decrease infections by prophylactic administration of topical or systemically absorbed antifungal agents in immunocompromised patients. The use of systemically absorbable agents such as azole antifungal agents appears to decrease the risk of invasive fungal infections.[7,51,52]

Fluconazole (400 mg/day), posaconazole (200 mg 3 times daily), or micafungin (50 mg daily) from the start of the conditioning regimen until day 75, can reduce the frequency of invasive *Candida* infections and decrease mortality at day 110 in patients undergoing allogeneic bone marrow transplantation.[7,52,53] Intravenous caspofungin (50 mg daily) was compared with intravenous itraconazole (200 mg twice daily for 2 days, then 200 mg once daily). Mortality was similar in both groups. Micafungin 50 mg daily was compared to intravenous fluconazole 400 mg daily in patients undergoing HSCT. Significantly fewer patients in the micafungin arm versus the fluconazole arm required empiric antifungal therapy, and mortality was decreased, although not significantly, in the micafungin arm. Based on this limited data, micafungin and caspofungin may provide options for prophylaxis in patients undergoing HSCT. However, more compelling data have been demonstrated with posaconazole.[12] In a double-blinded, multi-center clinical trial of the prophylaxis of invasive fungal infections in patients who had undergone HSCT with GVHD, posaconazole (200 mg every 8 hours), was superior to fluconazole (400 mg daily) in preventing aspergillosis and comparable to fluconazole in preventing other breakthrough invasive fungal infections.[56,57]

In less risk-selected patients with hematologic malignancies who are undergoing remission-induction chemotherapy, fluconazole (400 mg/day), posaconazole (200 mg 3 times daily), or caspofungin (50 mg daily), during induction chemotherapy for the duration of neutropenia, are effective in preventing systemic infection and death caused by *Candida* species.[7,54,55] Itraconazole cyclodextrin (2.5 mg/kg orally twice daily) is an option for less risk-selected patients, but it offers little advantage over other agents and is less well tolerated.

For solid-organ transplant recipients, fluconazole (200–400 mg [3–6 mg/kg] daily) or liposomal amphotericin B (1 to 2 mg/kg daily for 7 to 14 days) is recommended as postoperative antifungal prophylaxis for liver, pancreas, and small bowel transplant recipients at high risk of candidiasis.[7,35]

The use of prophylactic fluconazole (400 mg [6 mg/kg] daily) can decrease the incidence of fungal infections in select high-risk groups of patients. However, despite decreases in the rate of invasive candidiasis, to date, no mortality benefit has been demonstrated in any clinical trial. Widespread use of prophylactic fluconazole in all ICU patients is not warranted and may lead to an increase in resistance and adverse events. If utilized, prophylactic fluconazole should target high-risk patients with a presumed risk of invasive candidiasis of 10% to 15%.[7,34]

Empirical Therapy for Febrile Neutropenic Patients

Many clinicians advocate early institution of empirical IV amphotericin B in patients with neutropenia and persistent (>5 to 7 days) fever.[57] However, the potential toxicities (particularly nephrotoxicity) of this agent preclude its routine use in all patients. Suggested criteria for the empirical use of amphotericin B include (a) fever of 5 to 7 days' duration that is unresponsive to antibacterial agents, (b) neutropenia of more than 7 days' duration, (c) no other obvious cause for fever, (d) progressive debilitation, (e) chronic adrenal corticosteroid therapy, and (f) indwelling intravascular catheters. In patients who fail therapy with amphotericin B, lipid formulations of amphotericin B can be used (3 to 5 mg/kg per day). Comparative trials have indicated that lipid formulations of amphotericin B can be used as alternatives to amphotericin B deoxycholate for empirical therapy. Although they do not appear to be substantially more effective, there is less drug-related toxicity (Table 130–10).[57]

TABLE 130-10 Comparative Trials for Empiric Therapy in the Febrile Neutropenic Host

Year Published	Study Drugs	Study Design	Results and Comments
1982	Placebo vs. amphotericin B	Randomized	Favored amphotericin B
1989	Placebo vs. amphotericin B	Randomized	Favored amphotericin B
1996	Fluconazole vs. amphotericin B	Randomized	Defervescence: equivalence; safety analysis favored fluconazole
1998	Fluconazole vs. amphotericin B	Randomized	Composite: equivalence; secondary analysis favored fluconazole
2000	Fluconazole vs. amphotericin B	Randomized	Composite: equivalence; safety analysis favored fluconazole
1999	liposomal amphotericin B vs. amphotericin B	Randomized, double blind	Composite: equivalence; secondary analysis favors liposomal amphotericin B
2000	liposomal amphotericin B vs amphotericin B lipid complex	Randomized, double blind	Liposomal amphotericin B had superior safety vs. amphotericin B lipid complex and a similar therapeutic success rate
2001	Itraconazole vs. amphotericin B	Randomized, open label	Composite: equivalence; secondary analysis favors itraconazole
2002	Voriconazole vs. liposomal amphotericin B	Randomized, open label	Composite: equivalence; secondary analysis variable (voriconazole failed to meet criteria for noninferiority); Fewer breakthrough infections with voriconazole.
2004	Caspofungin vs. liposomal amphotericin B	Randomized, double blind	Composite: equivalence; secondary analysis favored caspofungin for treatment of baseline infections
2005	Liposomal amphotericin B loading regimen (10 mg/kg/day ×14 day) vs. standard dosing (3 mg/kg/day)	Randomized, prospective, double blind	Loading regimen did not demonstrate any benefit in overall response or survival and was associated with higher rates of nephrotoxicity and hypokalemia

Data from Boogaerts et al.,[58] Winstan et al.,[59] Marr,[60] Walsh et al.,[61] Cornely et al.,[80] and Walsh et al.[86]

Itraconazole and fluconazole have demonstrated efficacy equivalent to that of deoxycholate amphotericin B in patients with hematologic malignancy (not treated with allogeneic hematopoietic stem cell transplantation).[58–60] However, as fluconazole is not active against filamentous fungi, its use in patients at high risk for these pathogens should be avoided. If itraconazole is used, the intravenous formulation should be used because the bioavailability of the oral formulations (including the solution) is unreliable, however it is no longer available. Voriconazole and caspofungin were compared with liposomal amphotericin B in large randomized, multicenter trials of empirical antifungal therapy in febrile neutropenic patients. Voriconazole did not fulfill the protocol-defined criteria for noninferiority (a difference in success rates between voriconazole and amphotericin B of no more than 10 percentage points) to liposomal amphotericin; however, it was superior in reducing documented breakthrough infections, infusion-related toxicity, and nephrotoxicity. Patients who received voriconazole had more frequent episodes of transient visual disturbances and hallucinations. Caspofungin demonstrated equivalent efficacy but was superior in the successful treatment of baseline invasive fungal infections.[12,61]

Specific Therapy

Amphotericin B, the azoles, and the echinocandins have roles in the treatment of hematogenous candidiasis, and the choice of therapy is guided by weighing the greater activity of amphotericin B for some non-*albicans* species (e.g., *C. krusei*) against the lower toxicity and ease of administration of fluconazole and the echinocandins.[7]

Most clinicians recommend amphotericin B in total dosages of 0.5 to 1 g administered over approximately 1 to 2 weeks in patients with *Candida* endophthalmitis and in all neutropenic patients with candidemia.[13] Longer courses of therapy can be needed in some patients.[13] Fluconazole and amphotericin B appear similarly effective for the treatment of *C. albicans* bloodstream infections in the neutropenic patient; controlled data, however, are lacking. In patients with uncomplicated *C. albicans* fungemia who have not received systemic prophylaxis with antifungal azoles, therapy with fluconazole 400 to 800 mg/ day IV can be considered.[62] However, in patients who have undergone allogeneic HSCT, the role of fluconazole is becoming more limited because of its widespread use for antifungal prophylaxis. In this setting, particularly if the patient has been treated previously with an azole antifungal agent, the possibility of microbiologic resistance must be considered.[7] Infections with fluconazole-resistant *Candida* species, including *C. glabrata*, *C. krusei*, and fluconazole-resistant *C. albicans*, or with *Aspergillus* species, are more likely.

CLINICAL CONTROVERSY

Because *C. glabrata* demonstrates reduced susceptibility in vitro to both fluconazole and amphotericin B, optimal therapy is unclear. Larger doses of fluconazole (800 mg/ day in a 70-kg patient) have been used in less critically ill patients or amphotericin B (≥0.7 mg/kg per day). However, observational studies demonstrated no difference in mortality in nonneutropenic patients administered fluconazole versus amphotericin B for bloodstream infections caused by *C. glabrata*.[40] In vitro, echinocandin antifungal agents appear very active against *C. glabrata.* Current guidelines recommend the use of echinocandins, instead of fluconazole, for the treatment of fungemia caused by *C. glabrata;* however, their usefulness in vivo has not been adequately assessed in controlled trials.[7,40]

In patients intolerant to amphotericin B or fluconazole, one of the lipid formulations can be used. In a randomized trial, amphotericin B lipid complex (ABLC) was found to be equivalent to 0.6 to 1 mg/kg per day of amphotericin B, and open-label therapy with amphotericin B colloid dispersion (ABCD) has been successful.

CANDIDURIA

Within the urinary tract, most common lesions are either *Candida* cystitis or hematogenously disseminated renal abscesses. *Candida* cystitis often follows catheterization or therapy with broad-spectrum antimicrobial agents. The diagnosis of *Candida* cystitis can be problematic because of the frequent presence of *Candida* pseudohyphae and yeast cells in urine specimens secondary to urethral colonization. The usefulness of urine colony counts or antibody coating techniques is questionable. The recovery of 10,000 organisms or visualization of both yeast and pseudohyphae from fresh midstream urine or from bladder urine obtained by single catheterization (not indwelling) is suggestive of genitourinary candidiasis. In most patients, the infection is asymptomatic and clears spontaneously without specific antifungal therapy.

Initial therapy of candidal cystitis should focus on removal of urinary catheters whenever possible. Changing the catheter will eliminate candiduria in only 20% of patients, whereas discontinuation will eradicate *Candida* in 40% of patients. Asymptomatic candiduria rarely requires therapy. Therapy should be used in symptomatic patients and in neutropenic patients, as well as in patients with renal allografts and those who will undergo urologic manipulation, because of the risk of dissemination.[63,64]

Fluconazole 200 mg/day for 14 days hastens the time to a negative urine culture as compared with placebo treatment, but 2 weeks after the end of therapy, the frequency of a negative urine culture remains the same with both treatments.[64] Short courses of therapy are not recommended; treatment should include removal of catheters and stents whenever possible plus 7 to 14 days of therapy. Bladder irrigation with amphotericin B (50 mg in 500 mL sterile water instilled twice daily into the bladder via a three-way catheter) is only transiently effective. Minimal quantities (<3%) of amphotericin B are absorbed systemically from the bladder.[17,64]

ROLE OF CATHETER REMOVAL

Although it is common practice in today's standard of care to place indwelling catheters in patients for the administration of medications and parenteral nutrition (PN), catheter-related infections are a common complication. These foreign bodies (especially triple-lumen catheters) double as entry ports for normal skin flora or other nosocomial pathogens, and they provide a readily available site for the binding of pathogens through microbiotic biofilms. Their subsequent role as a source of bloodstream infections is facilitated by frequent use, PN, and the potential for contamination of catheters by medical staff who are colonized with *Candida* species.

Most consensus recommendations urge that, if feasible, initial non-medical management should include removal of all existing tunneled central venous catheters (CVCs) and implantable devices, particularly in patients with fungemia caused by *C. parapsilosis*, which is very frequently associated with catheters.[7] Arguments against the removal of all catheters in patients with candidemia include the prominent role of the gut as a source for disseminated candidiasis, the significant cost and potential for complications, and the problems that can be encountered in patients with difficult vascular access.[65] However, in an individual patient it is often difficult to determine the relative contribution of gut versus catheter

as the primary source of fungemia. The evidence for this recommendation is weakest in cancer patients with severe neutropenia and mucositis (e.g., acute leukemia, stem cell transplant), in whom candidemia is almost always primarily of gut origin, and removal of CVCs is least likely to have an impact on mortality. Nucci and Anaissie[62] have proposed that CVCs be removed in nonneutropenic patients without a short life expectancy who have one of the following criteria: (a) otherwise unexplained hemodynamic instability, (b) lack of clinical improvement or resolution of candidemia after more than 72 hours of an optimal dose of an appropriate antifungal agent, (c) established or at high risk for endocarditis or septic thrombophlebitis, or (d) a pocket infection or cellulitis. In patients with more than one CVC, they recommend removal if one tunneled or implanted CVC is the likely source of infection and the patient meets the preceding criteria.[62]

ASPERGILLOSIS

EPIDEMIOLOGY

Aspergillus is a ubiquitous mold that grows well on a variety of substrates, including soil, water, decaying vegetation, moldy hay or straw, and organic debris. Although more than 300 species of *Aspergillus* have been characterized, three species are most commonly pathogenic: *Aspergillus fumigatus, Aspergillus flavus*, and *Aspergillus niger*. The varying degrees of pathogenicity of each species depend on their relative geographic prevalence, conidial size and shape, thermotolerance, and production of mycotoxins. For example, transport of *A. fumigatus* conidia into the lungs is facilitated by their smaller diameter in comparison with *A. flavus* and *A. niger*.

9 The term *aspergillosis* may be broadly defined as a spectrum of diseases attributed to allergy, colonization, or tissue invasion caused by members of the fungal genus *Aspergillus*. A single satisfactory classification system for these disease entities is difficult because different populations of patients can develop the same type of infection. For example, osteomyelitis can result from local trauma or hematogenous dissemination in an immunocompromised host. Colonization in normal hosts can lead to allergic diseases ranging from asthma to allergic bronchopulmonary aspergillosis or, rarely, invasive disease.[66]

PATHOPHYSIOLOGY

Aspergillosis generally is acquired by inhalation of airborne conidia that are small enough (2.5 to 3 microns) to reach alveoli or the paranasal sinuses. Each conidiophore releases 10^4 conidia that remain suspended for long periods and are viable for months in dry locations. Although some authors advocate monitoring of hospital air for *Aspergillus* conidia, guidelines for interpreting results do not exist. The use of high-efficiency particulate air (HEPA) filters in operating rooms and laminar flow rooms and removal of immunocompromised patients from hospital renovation sites can be helpful in preventing infection in this population. Although the fate of *Aspergillus* conidia in the GI tract has not been closely studied, limited evidence suggests that this route may provide an important portal of entry for disseminated infections in humans.[67]

Superficial Infection

Superficial or locally invasive infections of the ear, skin, or appendages often can be managed with topical antifungal therapy. Skin infections in patients with burn wounds, although uncommon, can progress to deep-tissue invasion despite the use of topical or parenteral antifungal agents. Risk factors for deep infection include extensive thermal injuries, malnutrition, cirrhosis, and previous infection with *Pseudomonas aeruginosa*.[67]

Allergic Bronchopulmonary Aspergillosis

Allergic manifestations of *Aspergillus* range in severity from mild asthma to allergic bronchopulmonary aspergillosis (BPA). BPA, which is almost always caused by *A. fumigatus*, is characterized by severe asthma with wheezing, fever, malaise, weight loss, chest pain, and a cough productive of blood-streaked sputum. Following recurrent episodes of severe asthma, the disease usually progresses to fibrosis and bronchiectasis with granuloma formation. When *Aspergillus* conidia become trapped in the viscous mucus of asthmatic patients, BPA develops. The fungus grows, releasing toxins and antigens. The resulting host sensitization results in a variety of immune reactions. Early in the course of disease, an immunoglobulin E (IgE)-mediated (type I) immune reaction results in bronchospasm, eosinophilia, and immediate skin reactivity. The ensuing fibrosis and pulmonary infiltrates appear to be mediated by circulating or precipitating antibody complexes of IgG antibody, followed by granuloma formation and mononuclear infiltration because of a type IV delayed hypersensitivity reaction. Therapy is aimed at minimizing the quantity of antigenic material released in the tracheobronchial tree. Management of acute asthma attacks minimizes trapping of *Aspergillus* by bronchial secretions, and administration of parenteral corticosteroids clears lung infiltrates.[67] Antifungal therapy generally is not indicated in the management of allergic manifestations of aspergillosis, although some patients have demonstrated a decrease in their corticosteroid dose following therapy with itraconazole. A double-blind, randomized, placebo-controlled trial showed that itraconazole 200 mg orally twice daily for 16 weeks resulted in significant differences in the amelioration of disease, as measured by the reduction in corticosteroid dose and improvement in exercise tolerance and pulmonary function.[66]

Aspergilloma

In the nonimmunocompromised host, *Aspergillus* infections of the sinuses most commonly occur as saprophytic colonization (aspergillomas or "fungus balls") of previously abnormal sinus tissue. An aspergilloma is composed of intertwined *Aspergillus* hyphae matted together with fibrin, mucus, and cellular debris. Infection usually is localized in the maxillary sinus and rarely is associated with local invasion of adjacent bone or brain tissue. Sinus aspergillosis also can present as allergic sinusitis with nasal drainage of brownish mucous plugs. Therapy with corticosteroids and surgery generally is successful. In the immunocompromised host, subacute, chronic, or fulminant invasive disease can be seen, and a combination of antifungal and surgical therapy generally is required.[67,68]

Pulmonary aspergillomas are fungus balls arising in preexisting cavities because of tuberculosis, histoplasmosis, lung tumors, or radiation fibrosis, although occasionally no previous pulmonary disease is present. The diagnosis of aspergilloma generally is made on the basis of chest radiographs, on which aspergillomas appear as a solid rounded mass, sometimes mobile, of water density within a spherical or ovoid cavity and separated from the wall of the cavity by an airspace of variable size and shape. Patients generally experience chest pain, dyspnea, and sputum production. Hemoptysis is observed in 50% to 80% of patients, probably because of ulceration of the epithelial lining of the cavity with formation of granulation tissue, and hemoptysis is the cause of death in up to 26% of patients with aspergilloma. A poor prognosis is associated with increasing size or number of aspergillomas, immunosuppression (including corticosteroids), increasing *Aspergillus*-specific titers, underlying sarcoidosis, and HIV infection. Although *Aspergillus* can be

cultured in only 50% to 60% of patients, precipitating antibodies are positive in virtually 100% of patients.

Invasive disease occurs rarely, and therapy therefore is controversial. There are no controlled clinical trials with which to guide therapy, and recommendations for treatment have been generated from uncontrolled trials and case reports.[68] Concern regarding the risk of severe hemorrhage has led some clinicians to use aggressive surgical excision of aspergillomas or pulmonary resection in patients with hemoptysis. Complications, including bronchopulmonary fistulas, hemorrhage, empyema, and persistent airspace problems, have led to the recommendation that surgical intervention be reserved for patients with severe (>500 mL/24 h) hemoptysis, however. Bronchial artery embolization (BAE) has been used to occlude the vessel that supplies the bleeding site in patients experiencing hemoptysis. Unfortunately, BAE generally is unsuccessful or only temporarily effective. Collateral circulation eventually develops, supplying blood flow to the affected area, and hemoptysis often recurs; consequently, reembolization is often unsuccessful. BAE should be used as a temporizing procedure in a patient with life-threatening disease who might respond to more definitive therapy if hemoptysis is stabilized. Mild to moderate hemoptysis should be managed conservatively. Although IV amphotericin B generally is not useful in eradicating aspergillomas, inhaled or intracavitary instillation of amphotericin B has been employed successfully in a limited number of patients. Itraconazole has been efficacious in uncontrolled studies; however, the dose and duration of therapy have not been standardized. Hemoptysis generally ceases when the aspergilloma is eradicated.[67,68]

Invasive Aspergillosis

Although exposure to *Aspergillus* conidia is nearly universal, impaired host defenses are required for the development of invasive disease. Phagocytes (neutrophils, monocytes, and macrophages) rather than antibodies or lymphocytes constitute the primary host defense system against invasive disease with aspergillosis. Macrophages prevent germination of conidia and also eradicate conidia, providing the first line of defense against invasive disease. Administration of corticosteroids appears to impair the killing of conidia by macrophages and to impair mobilization of neutrophils. Neutrophils halt hyphal growth and dissemination and kill mycelia, constituting a second line of defense. Prolonged neutropenia appears to be the most important predisposing factor to the development of invasive aspergillosis, accounting for the high frequency of disease in patients with acute leukemia. Complement provides a source of chemotactic factor and facilitates neutrophil damage to hyphae and monocyte killing of conidia. Complement is not necessary for the attachment or ingestion of conidia by human alveolar macrophages.[67,69]

Aspergillosis is an uncommon fungal infection in patients with AIDS. AIDS patients may be at less risk for aspergillosis than other fungal infections because the primary cellular defect in AIDS patients is in the T-lymphocytes, whereas neutrophils and macrophages constitute the primary lines of defense to infection with aspergillosis. Aspergillosis was reported as a late complication of disease in AIDS patients with additional risk factors for aspergillosis, such as corticosteroid use, neutropenia, previous *Pneumocystis carinii* or cytomegalovirus pneumonia, marijuana smoking, or the use of broad-spectrum antibiotics. However, approximately 50% of patients with aspergillosis have no classic risk factors. The majority of these patients had CD4 counts < 50 cells/mm^3. Although some patients diagnosed early in their infection responded to treatment, most patients do not respond to therapy with amphotericin B 0.5 mg/kg per day or itraconazole 200 to 600 mg/day.[70]

Invasive disease with *Aspergillus* can arise de novo or from any of the allergic or colonizing forms of aspergillosis. Predisposing factors to the development of invasive aspergillosis include glucocorticoid therapy, particularly following chronic administration or with higher dosages (30 to 200 mg/day of prednisone), cytotoxic agents, and recent or concurrent therapy with broad-spectrum antimicrobial agents. Patients with chronic hepatitis, alcoholism, diabetes mellitus, chronic granulomatous disease, leukopenia (<1000 cells/mm^3), leukemia (particularly acute lymphocytic or myelogenous leukemia), lymphoma, and acute rejection of an organ transplant are also at a higher risk of invasive disease. Although rare, invasive aspergillosis has been reported in apparently normal hosts.[67]

CLINICAL PRESENTATION[67,68]

The lung is the most common site of invasive disease. In the immunocompromised host, aspergillosis is characterized by vascular invasion leading to thrombosis, infarction, necrosis of tissue, and dissemination to other tissues and organs in the body. Survival beyond 2 or 3 weeks is uncommon. If bone marrow function returns, cavitation of the pulmonary lesion generally occurs, and the spread of infection can be halted. The progressive nature of the disease and its refractoriness to therapy are, in part, caused by the organism's rapid growth and its tendency to invade blood vessels.

Signs and Symptoms

Patients often present with classic signs and symptoms of acute pulmonary embolus: pleuritic chest pain, fever, hemoptysis, and friction rubs. The CNS, liver, spleen, heart, GI tract, pericardium, and other body sites are involved in a substantial minority of cases. In neutropenic patients with *Aspergillus* pneumonia, hyphae invade the walls of bronchi and surrounding parenchyma, resulting in an acute necrotizing, pyogenic pneumonitis. As a result, patients often present with classic signs and symptoms of acute pulmonary embolus: pleuritic chest pain, fever, hemoptysis, and friction rubs.

Diagnosis

The diagnosis of aspergillosis is complicated by the presence of *Aspergillus* as a normal commensal in the human GI tract and respiratory secretions, and establishment of a definitive diagnosis of disease is difficult. Although suggestive of infection, the presence of hyphae in a smear or biopsy specimen is not diagnostic. Demonstration of *Aspergillus* by repeated culture and microscopic examination of tissue provides the most firm diagnosis. The appearance of *Aspergillus* in tissues varies with increasing host resistance from the normal vegetative hyphae found with necrotic tissue and exudate in the alveoli of immunocompromised hosts to the compact, tangled filaments (*granules*) observed in fungal balls. Identification of *Aspergillus* generally is based on the appearance of 2- to 4-micron-wide septate hyphae that are dichotomously branched at 45-degree angles. Sporulation is observed rarely in tissue. Although growth on Sabouraud dextrose or brain-heart infusion agar can be used for primary culture, bronchoscopy or bronchoalveolar lavage cultures are positive in only 40% of histopathologically identified specimens. Blood, CSF, and bone marrow cultures are rarely positive for *Aspergillus*.

Many clinicians treat positive respiratory cultures of *Aspergillus* as a common contaminant and argue that a minimum of two to three positive cultures is necessary before antifungal therapy is indicated. Any positive culture, however, can be indicative of true infection in the immunocompromised host, and the positive predictive value can be as high as 80% to 90% in patients with leukemia or bone marrow transplants.

Diagnostic Tests Galactomannan is a cell-wall polysaccharide specific to *Aspergillus* species that is detectable in serum and other body fluids during invasive aspergillosis (IA). Galactomannan levels, reported as optical density values, can be measured in body fluids by means of a double-sandwich enzyme immunosorbent assay (EIA).

The Platelia *Aspergillus* EIA test (Bio-Rad Laboratories) is FDA-approved for use in the diagnosis of invasive aspergillosis in HSCT recipients and in patients with leukemia; its usefulness in solid-organ transplant and pediatric populations need to be established. The use of mold-active antifungals can decrease the sensitivity of the test. In most patients, circulating antigen can be detected at a mean of 8 days before diagnosis by other means. However, false-positive galactomannan assay results have been reported for patients receiving piperacillin-tazobactam and amoxicillin-clavulanate, those with bifidobacteria infections, and in neonates.[14]

The BG test (Fungitell; Associates of Cape Cod) detects (1,3)-β-D glucan (BG) in the serum of patients with symptoms of or medical conditions predisposing to invasive fungal infections and aids in the diagnosis of deep-seated mycoses and fungemia. BG is a cell-wall constituent of many pathogenic fungi, including *Aspergillus* and *Candida* species, and is detectable in patients' serum during invasive disease due to these organisms. In addition to patients with IA and candidiasis, BG is also detectable in patients with infections caused by species of *Fusarium, Trichosporon, Saccharomyces*, and *Acremonium*, which are less common but very important fungal pathogens, especially in immunocompromised hosts. Detection of BG in serum uses a chromogenic variant of the limulus amoebocyte lysate assay. Although a positive test result for the presence of BG does not identify the infecting fungus, the practical application of this test includes its use as a screening assay (presumptive marker) for invasive fungal infection to allow the earlier initiation of antifungal therapy. Other tests are necessary for the confirmation and identification of the fungal pathogen.[14]

Late findings on radiographic studies include wedge-shaped pleural-based infiltrates or cavities on chest radiographs. Findings on computed tomographic (CT) scans include the halo sign (an area of low attenuation surrounding a nodular lung lesion) initially (caused by edema or bleeding surrounding an ischemic area) and, later, the crescent sign (an air crescent near the periphery of a lung nodule caused by contraction of infarcted tissue). CT abnormalities are best documented in neutropenic marrow transplant recipients and commonly precede plain chest radiograph abnormalities.

TREATMENT

Invasive Aspergillosis

Therapy for invasive aspergillosis is far from optimal at this time in part because of the difficulties in establishing a diagnosis and in part because of a lack of truly effective antifungal agents. Administration of amphotericin B appears to decrease mortality from more than 90% to approximately 45%. These data, however, are difficult to interpret because many patients were diagnosed postmortem, or amphotericin B therapy was not administered until the patient had very advanced disease. Mortality from pulmonary aspergillosis in bone marrow transplant recipients exceeds 94% regardless of therapy.[67] Although early diagnosis and administration of antifungal therapy can result in higher response rates, correction of underlying immune deficits (in particular, return of neutrophil counts) is of paramount importance in eradication of infection.[68]

Until the diagnosis of aspergillosis can be determined more rapidly and definitively, empirical therapy must be instituted when invasive disease is suspected. In patients at highest risk for invasive disease (acute leukemia and bone marrow transplant recipients), the most important predisposing factors include prolonged severe neutropenia (<100 cell/microliter for more than 1 week), graft rejection, chronic administration of corticosteroids, and tissue damage from preexisting infection. In these patients, antifungal therapy should be instituted in any of these conditions: (a) persistent fever or progressive sinusitis unresponsive to antimicrobial therapy, (b) an eschar over the nose, sinuses, or palate, (c) the presence of characteristic radiographic findings, including wedge-shaped infarcts, nodular densities, and new cavitary lesions, or (d) any clinical manifestation suggestive of orbital or cavernous sinus disease or an acute vascular event associated with fever. Isolation of *Aspergillus* species from nasal or respiratory tract secretions should be considered confirmatory evidence in any of the previously mentioned clinical settings.[67]

NON–HIV-INFECTED PATIENT

Prophylaxis

Unfortunately, effective chemoprophylaxis against infections by *Aspergillus* species has not been demonstrated thus far.[7] As noted above in the discussion of prophylaxis for *Candida* infections in immunocompromised hosts, prophylaxis with azoles or echinocandins can reduce the incidence of fungal infections in select high-risk populations.

Specific Therapy

Even though older azole antifungal agents (miconazole and ketoconazole) possess poor in vitro activity against *Aspergillus* species, newer triazoles demonstrate improved activity both in vitro and in animal models of infection.[71] Voriconazole has emerged as the drug of choice of most clinicians for primary therapy of most patients with invasive aspergillosis.[72] A randomized trial, which compared voriconazole with amphotericin B (followed by other licensed antifungal therapy) for primary therapy of aspergillosis, noted better responses, improved survival, and fewer severe side effects with voriconazole.[73]

In patients who are unable to tolerate voriconazole, amphotericin B can be used. Because *Aspergillus* is only moderately susceptible to amphotericin B, full doses (1 to 1.5 mg/kg/day) are generally recommended, with response measured by defervescence and radiographic clearing. To treat microfoci, therapy should be continued after resolution of clinical and radiographic abnormalities until cultures (if they can be obtained) are negative, and reversible underlying predispositions have abated. Clinical response rather than any arbitrary total dose should guide duration of therapy. The optimal dosage or duration of amphotericin B therapy for the treatment of invasive disease is unknown and dependent on the extent of disease, the response to therapy, and the patient's underlying disease(s) and immune status. Unfortunately, the response rate averages only 37% (range, 14% to 83%), and the response to therapy is largely related to the extent of aspergillosis at the time of diagnosis, and host factors, such as resolution of neutropenia and the return of neutrophil function, lessening immunosuppression, and the return of graft function from a bone marrow or organ transplant.

Lipid formulations of amphotericin B can be indicated in patients with impaired renal function, and in those patients who develop nephrotoxicity while receiving deoxycholate amphotericin B. The lipid-based formulations may be preferred as initial therapy in patients with marginal renal function or in patients receiving other nephrotoxic drugs. Although these preparations appear less toxic than standard preparations, only limited data regarding their relative efficacy for invasive aspergillosis are available at this time,

as the studies with the lipid preparations have been open-label or with historical conventional amphotericin B controls.[70,74]

Caspofungin was approved by the FDA for use as salvage therapy in patients who are intolerant or who fail therapy with one of the amphotericin B formulations.[12] Caspofungin has in vitro activity against *Aspergillus* species and is indicated for the treatment of invasive aspergillosis in patients who are refractory to or intolerant of other therapies such as conventional amphotericin B, lipid formulations of amphotericin B, and/or itraconazole. Caspofungin has not yet been studied as first-line therapy for patients with aspergillosis. Because of the high risk of mortality from invasive aspergillosis even following treatment with standard therapy such as amphotericin B or itraconazole, caspofungin can offer a new mechanism for salvage therapy for patients with this disease.

The use of adjuvant therapies, such as granulocyte transfusions or recombinant colony-stimulating factors, remains controversial, and controlled trials are lacking at this time. Although some authors advocate combination therapy with azoles, flucytosine, or rifampin plus amphotericin B, controlled clinical studies verifying the efficacy of these combination therapies are lacking.

Secondary Prophylaxis

The use of prophylactic antifungal therapy to prevent primary infection or reactivation of aspergillosis during subsequent courses of chemotherapy is controversial.[18] Studies assessing the utility of IV administration of amphotericin B in low doses (0.1 mg/kg per day) as prophylactic therapy or with higher dosages (0.5 to 0.6 mg/kg per day) as empirical therapy for invasive fungal infections in patients with granulocytopenia have not included sufficient numbers of patients to enable detection of differences in the number of *Aspergillus* infections.

The prophylactic use of intranasal amphotericin B aerosol sprays (5 or 10 mg/day in three divided doses) appeared beneficial in small studies in human and animal models. A larger randomized trial found, however, that amphotericin B sprays reduced colonization of the nasal mucosal without any reduction in the frequency of invasive pulmonary infections with aspergillosis. Because failure of amphotericin B sprays can be a result of the ability of small airborne conidia to access the alveolar spaces directly and to establish infection, use of aerosolized forms of amphotericin B capable of reaching the alveolar spaces can be required.

In granulocytopenic patients who recover from an episode of invasive aspergillosis, the risk of relapse of aspergillosis during subsequent courses of chemotherapy is greater than 50%. Secondary prophylaxis of aspergillosis with empirical administration of high-dose amphotericin B decreases the risk of relapse. Amphotericin B 1 mg/kg per day is started 24 to 48 hours prior to the start of chemotherapy and continued throughout the period of granulocytopenia. Some investigators recommend the addition of flucytosine (dosed to achieve peak serum concentrations of 30 to 60 mcg/mL) to the amphotericin B regimen. Although the use of itraconazole (alone or in combination with amphotericin B or flucytosine) can be beneficial in this patient population, little is known regarding its efficacy in this setting. If itraconazole is administered, serum levels should be monitored to assess absorption because poor absorption of drug has been documented in this patient population.[12]

EMERGING PATHOGENS

The increased frequency of fungal pathogens that were once rare is gaining attention from the medical community. Permissive environmental conditions, selective antifungal pressure, and increased numbers of immunosuppressed patients have led to increased numbers of infections caused by the Zygomycetes (e.g., *Mucor*, *Rhizopus* spp., or *Absidia*) or filamentous fungi such as *Scedosporium* or *Fusarium* species. Unfortunately, the early presentation of *Fusarium* and *Scedosporium* infections often mimics that of aspergillosis. On histopathology, *Scedosporium* species resembles *Aspergillus* species with dichotomously branching, septate hyphae and has a tendency for invasion of vascular structures.[75] These pathogens often demonstrate intrinsic resistance to amphotericin B and are associated with high mortality rates.[73] For example, mortality caused by *Scedosporium prolificans*, previously known as *Scedosporium inflatum*, exceeds 85%; *Scedosporium apiospermum* (the asexual state of *P. boydii)*, was uniformly fatal in 23 solid-organ transplant recipients with disseminated disease.[75] However, in vitro data suggest that *S. prolificans* is more sensitive to voriconazole than to amphotericin B or itraconazole.[75,76] Voriconazole recently received FDA approval for the treatment of serious fungal infections caused by *S. apiospermum* and *Fusarium* species, including *Fusarium solani*, in patients intolerant of or refractory to other therapy.[77] Posaconazole appears promising for the treatment of zygomycoses infections.

ANTIFUNGAL THERAPY

The antifungal armamentarium for the treatment of invasive fungal infections includes (a) inhibitors of the fungal cell membrane, such as polyenes (e.g., amphotericin B) and azole antifungals, (b) inhibitors of DNA (5-flucytosine), and more recently, (c) inhibitors of cell wall biosynthesis (echinocandins).[78]

Antifungal therapy generally uses one or more of these agents, depending on the severity of infection and the patients' immune status. Rarely are the agents used in combination. Often therapy is initiated with an intravenous agent such as amphotericin B, and therapy is changed to an oral (azole) regimen as the patient's clinical status improves and oral therapy is tolerated. The most widely used combination therapy consists of flucytosine plus amphotericin B. The role of combination therapy is unclear at this time; controlled trials are lacking and the possibility of therapeutic antagonism when using azoles in combination with amphotericin B remains debated. Controlled trials are needed to define the role of azoles plus amphotericin B and azoles or amphotericin B plus an echinocandin.

AMPHOTERICIN B

Amphotericin B remains the therapy of choice for many systemic fungal infections despite a lack of controlled clinical trials documenting the optimal dosage, duration of therapy, or relative efficacy of this agent in comparison with newer azole antifungal agents. During pregnancy, amphotericin B remains the treatment of choice for most fungal infections because azole antifungals are teratogenic.[17,79]

The side effects of amphotericin B generally are categorized as acute (infusion-related) or long term. Gallis and Drew[17] recently reviewed the side effects and clinical uses of amphotericin B.

LIPID FORMULATIONS OF AMPHOTERICIN B

The use of deoxycholate amphotericin B frequently is associated with the development of induced nephrotoxicity. In an attempt to decrease the incidence of nephrotoxicity, three lipid formulations of amphotericin B have been developed and approved for use in humans: amphotericin B lipid complex (ABLC, Abelcet; Enzon Pharmaceuticals), amphotericin B colloidal dispersion (ABCD, Amphotec; Intermune Pharmaceuticals), and liposomal amphotericin B (AmBisome; Gilead Pharmaceuticals). In these preparations,

amphotericin B is incorporated into the phospholipid bilayer membrane rather than in the enclosed aqueous phase.

The various lipid formulations of amphotericin B exhibit markedly different pharmacokinetics; however, the clinical implications of these differences remain unclear. Although larger doses of these preparations are required to achieve similar pharmacologic effects as the deoxycholate form of amphotericin B, the toxicity appears to be much lower.[79] Although the FDA-approved dosages of these agents are 5 mg/kg per day (amphotericin B lipid complex), 3 to 6 mg/kg per day (amphotericin B colloid dispersion), and 3 to 5 mg/kg per day (liposomal amphotericin B), the agents appear generally equipotent. The optimal dose of these compounds for serious *Candida* infections is unknown; however, dosages of 3 to 5 mg/kg per day appear reasonable. Liposomal amphotericin B administered at 3 mg/kg per day was equally as effective but less toxic than a dosage of 10 mg/kg per day as initial therapy for invasive mold infections.[80] The relative efficacy of these agents is unknown; whether differences in pharmacokinetic features result in different outcomes in the treatment of specific types of infections (e.g., CNS infections) is unclear.[7]

Lipid formulations of amphotericin B are indicated for patients intolerant of, refractory to, or at high risk of being intolerant to conventional antifungal therapy.[7,81] Intolerance generally is defined as initial renal insufficiency (creatinine >2.5 mg/dL or creatinine clearance <25 mL/min), a significant increase in creatinine (to 2.5 mg/dL for adults or 1.5 mg/dL for children), or severe acute administration-related toxicity, whereas refractory infections are defined as therapeutic failure of more than 500 mg amphotericin B.

Only ABLC and liposomal amphotericin B have been approved for use in proven candidiasis. Both in vivo and clinical studies indicate that these compounds are less toxic but as effective as amphotericin B when used in appropriate dosages. Nevertheless, their higher cost and the paucity of randomized trials in proven invasive candidiasis limit their front-line use in these infections.[81]

CLINICAL CONTROVERSY

Owing to the higher cost and paucity of randomized trials showing the efficacy of lipid-associated formulations of amphotericin B against proven invasive candidiasis, many clinicians limit their first-line use for the treatment of these infections to individuals who are intolerant to, at high risk of intolerance to, or refractory to amphotericin B deoxycholate. However, the data demonstrating up to a 6.6-fold increase in mortality in patients with amphotericin B–induced nephrotoxicity have convinced other clinicians that high-risk patients (e.g., residence in an ICU care or intermediate care unit at the time of initiation of amphotericin B therapy) warrant first-line therapy with these agents.

CLINICAL CONTROVERSY

Should lipid formulations of amphotericin B be used rather than the traditional deoxycholate formulation? Many clinicians feel that lipid formulations have shown clear superiority in the treatment of aspergillosis and histoplasmosis and are "at least as good" as deoxycholate amphotericin B for the treatment of *Candida*, cryptococcosis, and febrile neutropenia. However, they lack FDA approval for these infections except (in some cases) as salvage therapy and their costs can be prohibitive.[81]

FLUCYTOSINE

Flucytosine (also known as 5-flucytosine) is a fluorinated pyrimidine analogue that is highly water-soluble. Patients with creatinine clearances of less than 40 mL/min should receive 100 to 150 mg/kg daily in four divided doses. The dosage should be reduced by 50% in patients with a creatinine clearance of 25 to 50 mL/min and by 75% in patients with a clearance of 13 to 25 mL/min. Peak serum concentrations (2 hours after an oral dose) should be monitored in all patients (particularly those with a creatinine clearance of less than 10 mL/min) to maintain peak serum concentrations of more than 100 mg/L.[24,25]

Flucytosine generally is associated with few side effects in patients with normal renal, GI, and hematologic function, although rash, GI discomfort, diarrhea (5% to 10%), and reversible elevations in hepatic enzymes are observed occasionally. In patients with renal dysfunction or concomitant amphotericin B therapy, leukopenia, thrombocytopenia, and (rarely) enterocolitis can occur. Although studies have suggested that little or no conversion of flucytosine to fluorouracil occurs in vitro, serum concentrations of greater than 1,000 ng/mL (therapeutic for the treatment of malignancies) have been documented in some patients. Investigators have theorized that flucytosine may be secreted into the GI tract, deaminated by intestinal bacteria, and reabsorbed as 5-fluorouracil.[24,25]

Flucytosine is used in combination with amphotericin B or fluconazole in the treatment of cryptococcosis or (less commonly) candidiasis. The rapid development of resistance to flucytosine, however, precludes its use as single-agent therapy. Mechanisms for drug resistance can include loss of deaminase and decreased permeability to the drug.[24,25]

ECHINOCANDINS

The echinocandins (caspofungin, micafungin, and anidulafungin) are a new class of antifungal agents that act as concentration-dependent, noncompetitive inhibitors of β(1,3)-D-glucan synthase, an essential component of the cell wall of susceptible filamentous fungi that is absent in mammalian cells.[12]

All echinocandins display linear pharmacokinetics following administration of intravenous dosages, and are degraded primarily by the liver (also in the adrenals and spleen) by hydrolysis and *N*-acetylation. Following initial distribution, echinocandins are taken up by red blood cells (micafungin) and the liver (caspofungin and micafungin) where they undergo slow degradation to mainly inactive metabolites, although two uncommon metabolites of micafungin possess antifungal activity. Degradation products are excreted slowly over many days, primarily through the bile. Among the echinocandins, anidulafungin is unique in being eliminated almost exclusively by slow chemical degradation rather than undergoing hepatic metabolism.[12]

Echinocandins are available only as parenteral formulations, are not dialyzable, and do not require dosage adjustment in patients with renal insufficiency. They have minimal CSF penetration, largely because of their high protein binding and large molecular weights, although the clinical relevance of these findings can be disputed, given that several other antifungal agents (amphotericin B and itraconazole) are effective for the treatment of fungal meningitis despite low CSF concentrations.

Adverse effects of echinocandins include histamine release resulting in rash, facial swelling, and itchiness. Limited experience suggests that caspofungin and micafungin are safe to use in pediatric patients; the safety and effectiveness of anidulafungin in pediatric patients has not been established. At the time of FDA approval, there were concerns regarding the safety of caspofungin when combined with cyclosporine. However, three retrospective

analyses of the use of caspofungin and cyclosporine in patients do not support a risk of clinically relevant hepatotoxicity.[12]

AZOLE ANTIFUNGAL AGENTS

The introduction of the azole antifungal agents has rapidly expanded the armamentarium of agents useful in the treatment of systemic fungal infections.[9] Adverse effects of azoles include GI disturbances (primarily nausea, vomiting, epigastric pain, and diarrhea), which appear to be more common in patients receiving ketoconazole and the solution formulation of itraconazole. Although cyclodextrin is not absorbed following oral administration, use of the IV formulations of itraconazole and voriconazole is limited to 2 weeks because of concerns for potential nephrotoxicity secondary to accumulation of the cyclodextrin vehicle.[82] Fluconazole is well tolerated; intestinal complaints are the most frequently reported, followed by headaches and rash. Unlike ketoconazole, fluconazole does not inhibit testicular or adrenal steroidogenesis in healthy volunteers or hospitalized patients. Reversible alopecia occurs not infrequently and usually appears after several months of treatment with higher doses of fluconazole. Azoles are potentially teratogenic and should be avoided in pregnant women.[82]

Itraconazole

Itraconazole is triazole antifungal with a broad spectrum of antifungal activity. Despite its marked structural similarity to ketoconazole, itraconazole differs in several important respects. Itraconazole appears to have greater specificity against fungal versus mammalian CYP, resulting in greater potency and a decrease in CYP-mediated side effects. In addition, itraconazole possesses excellent in vitro activity against *Aspergillus* and *Sporothrix* species.

Like ketoconazole, the capsule formulation of itraconazole depends on the availability of low gastric pH for dissolution and absorption. Administration with food appears to enhance significantly the bioavailability of itraconazole capsules, whereas it decreases the bioavailability of the oral solution. Because itraconazole exhibits pH-dependent dissolution and absorption, absorption of the capsule formulation is impaired in patients receiving antacids or H_2-receptor antagonists and in patients with achlorhydria.[82] Plasma concentrations of itraconazole following a single oral dose (capsules) in HIV-infected patients are approximately 50% lower than concentrations observed in healthy volunteers. The capsule formulation of itraconazole exhibits unpredictable oral bioavailability, particularly in subjects with hypochlorhydria and in patients with enteropathy caused by mucositis or graft-versus-host gut disease. An oral suspension formulation of itraconazole is available; that uses cyclodextrin as a solubilizing vehicle to increase the solubility of the drug. The oral bioavailability of the solution is unaffected by alterations in gastric pH or in patients with enteropathy.[7,82]

Fluconazole

Fluconazole is a triazole antifungal agent with markedly different pharmacologic features than other marketed azole antifungals. The small molecular weight, low protein binding, and increased water solubility of fluconazole result in rapid, essentially complete absorption of drug following oral administration. Because fluconazole is excreted primarily (>80%) as unchanged drug in the urine, dosage adjustments are necessary in patients with renal dysfunction.[71]

Voriconazole

The hepatic biotransformation of voriconazole is fairly complex and involves CYP2C19, CYP3A4, and CYP2C9, with most metabolism mediated through CYP2C19. Two of the CYPs involved in voriconazole metabolism (CYP2C19 and CYP2C9) exhibit genetic polymorphism; variability in the CYP2C19 genotype accounts for approximately 30% of the overall between-subject variability in voriconazole pharmacokinetics. About 3% to 5% of white and African human populations are poor metabolizers, while 15% to 20% of Asian populations are poor metabolizers. Drug levels can be as much as fourfold greater in poor metabolizers than in individuals who are homozygous extensive metabolizers. Coadministration of voriconazole with drugs that are potent CYP450 enzyme inducers can significantly reduce voriconazole levels. Voriconazole drug interactions are dose-dependent, as they exhibit unpredictable nonlinear pharmacokinetics; thus, drug interactions are more difficult to predict and manage.

The most common side effect of voriconazole is a reversible disturbance of vision (photopsia), which occurs in approximately 30% of patients but rarely leads to discontinuation of the drug. Symptoms tend to occur during the first week of therapy and decrease or disappear despite continued therapy. Patients experience altered color discrimination, blurred vision, the appearance of bright spots and wavy lines, and photophobia. Patients should be cautioned that driving can be hazardous because of the risk of visual disturbances. The visual effects are associated with changes in electroretinogram tracings, which revert to normal when treatment with the drug is stopped; no permanent damage to the retina has been demonstrated.[71]

CLINICAL CONTROVERSY

Controversy has arisen about whether single-drug therapy or combination therapy (e.g., voriconazole plus an echinocandin or voriconazole plus a lipid formulation of amphotericin B) is optimum therapy. At present, the highest interest concerns combination therapy in the treatment of aspergillosis, given the continued high mortality of these infections.[84] However, in vitro and animal data have produced conflicting results. Several retrospective studies have suggested an improvement in mortality with combination therapy with two or three antifungal agents; however, prospective, controlled human studies are lacking. Thus, there are as yet no firm recommendations regarding the use of such combinations in humans.[12]

Posaconazole

Posaconazole has a broad spectrum of antifungal activity, including *Aspergillus* and *Candida* species and zygomycetes. In vitro studies demonstrate that posaconazole is an inhibitor but not a substrate of hepatic (but not total) CYP3A4, and both a substrate and an inhibitor of P-glycoprotein (Pgp), suggesting that it may exhibit a drug interaction profile similar to other azoles. In addition, posaconazole undergoes glucuronidation by uridine diphosphate (UDP)-glucuronosyltransferase enzymes.[71]

DRUG INTERACTIONS WITH ANTIFUNGAL AGENTS

Drug interactions with azole antifungals generally can be placed into three broad categories: (a) decreases in azole bioavailability because of chelation or secondary to increases in gastric pH, (b) interactions with other CYP–metabolized drugs, and (c) interactions caused by inhibition of Pgp. Drug interactions in the latter two categories can result in increases or decreases in the azole antifungal, in the interacting drug, or in both drugs.

TABLE 130-11 Plasma Concentration Monitoring of Antifungal Agents[78,83,85]

	Serum Concentration Monitoring Necessary?	Target Concentration Range	Timing of Sample
Echinocandins	No	NA	NA
Amphotericin B (including lipids)	No	NA	NA
Fluconazole	No	NA	NA
Itraconazole	Yes, to ensure absorption and efficacy	>0.5 mcg/mL	Trough after 7 days of therapy
Voriconazole	Yes, (a) metabolism is variable, (b) low concentrations are associated with poor outcome, (c) high concentrations are associated with adverse effects (hepatotoxicity, visual disturbances)	Troughs >1 mcg/mL; concentrations >2.05 mcg/mL have been associated with improved outcomes; the likely therapeutic range is ~2–6 mcg/mL	Trough after 7 days of therapy
Posaconazole	Unclear; perhaps to ensure absorption	>0.25 mcg/mL ?	Trough after 7 days of therapy
Flucytosine	Yes–high concentrations (>100 mcg/mL) are associated with bone marrow suppression and hepatotoxicity	Peak concentration <100 mcg/mL	2-hour post-dose peak

NA, not applicable.

The interaction of azole antifungal agents with other CYP–metabolized drugs is well recognized. The azoles appear to be metabolized almost entirely via the CYP3A4 subfamily. As expected, they interact with other drugs metabolized partly or wholly through this enzyme pathway. In addition, fluconazole and voriconazole use the CYP2C19 pathway. Numerous clinically significant interactions have been documented with azole antifungals and a variety of other drugs. In most cases, the azole interferes with the metabolism of the other CYP–metabolized drug.[71]

The interaction between ketoconazole and cyclosporine has been exploited to reduce drug costs associated with administration of cyclosporine following organ transplantation. Relative to ketoconazole and itraconazole, fluconazole appears to be intermediate in its ability to inhibit human cytochromes P450. The magnitude of fluconazole-induced inhibition of cyclosporine metabolism appears, however, to depend on the dosage of fluconazole.

Predictably, drugs such as rifampin, rifabutin, isoniazid, phenytoin, and carbamazepine, which are known to induce the activity of cytochromes P450, result in increased metabolism of the azole antifungals and can result in therapeutic failures. Increased dosages of azole antifungals can be required in patients receiving these combinations of drugs.

Itraconazole is an inhibitor of intestinal Pgp. Significant increases in digoxin (a Pgp substrate) have been observed in patients receiving both agents concurrently. Interactions with other substrates of Pgp would be expected to occur.

Echinocandins are not inducers of cytochrome P450 enzymes, nor do they interact with Pgp, and are considered poor substrates of CYP3A4. Nevertheless, cyclosporine increases the area under the curve (AUC) of caspofungin by ~35%, and tacrolimus AUC, peak, and 12-hour concentrations are decreased by approximately 20% during concomitant administration with caspofungin. Additionally, when caspofungin was administered concurrently with tacrolimus, tacrolimus levels were reduced by 20% compared to administration with tacrolimus alone. The mechanism for these interactions is not yet known. Rifampin both inhibits (acutely) and induces (after chronic administration) caspofungin metabolism. A dosage increase is recommended in patients receiving other enzyme inducers, such as efavirenz, nevirapine, phenytoin, dexamethasone, and carbamazepine. Although micafungin does not significantly affect the clearance (or AUC) of tacrolimus, it increases the AUC of sirolimus by 21%, and of nifedipine by 18%, and decreases the clearance of cyclosporine by 16%. Monitoring of cyclosporine levels during combination therapy with micafungin is recommended. Administration of cyclosporine and anidulafungin revealed only a clinically insignificant 22% increase in the AUC of anidulafungin following 4 days of concomitant cyclosporine therapy, and concurrent administration of rifampin or a variety of other substrates, inhibitors, or inducers of CYP450 with anidulafungin does not affect its clearance.[12]

PLASMA CONCENTRATION MONITORING OF ANTIFUNGAL AGENTS

Routine monitoring of plasma concentrations of antifungal agents to assess efficacy or toxicity of these agents generally is not available. Correlations between plasma concentrations of antifungal agents and therapeutic outcomes have been poorly studied. Under certain circumstances, serum or plasma concentration monitoring is warranted, for example, in patients susceptible to flucytosine toxicity or to document adequate oral absorption of ketoconazole, itraconazole, or voriconazole in cases of suspected treatment failure, concern about compliance or absorption, or when drug interactions that might reduce the solubility or accelerate the metabolism of azoles are suspected (Table 130–11).[83]

CLINICAL CONTROVERSY

Although "therapeutic" levels have not been defined, some investigators recommend maintenance of serum concentrations of itraconazole (2 to 4 hours after administration) of 1 mcg/mL, measured by bioassay, and voriconazole.[18] Among AIDS patients, those receiving itraconazole dosages of 200 mg once or twice daily achieved median plasma concentrations of 3 or 6 mcg/mL, respectively.[18] Although pharmacokinetic-pharmacodynamic analysis of early clinical trials of voriconazole did not reveal an association between voriconazole concentration and efficacy, they did suggest a trend toward worse outcome in those patients with voriconazole concentrations of <0.5 mcg/mL. This lack of association is likely because the antifungal exposure far exceeded the MICs of most pathogens (MIC_{90}, ≤0.5 mcg/mL). However, in a recent study, favorable responses were observed in 10:10 patients with voriconazole plasma concentrations >2.05 mcg/mL, whereas disease progressed in 44% of patients with concentrations <2.05 mcg/mL.[85]

COMBINATION ANTIFUNGAL THERAPY FOR ASPERGILLOSIS

Based on extensive experience in the management of bacterial, and more recently, retroviral infections, the use of combination agents for synergistic or additive effects is now common practice,

particularly for the treatment of invasive aspergillosis.[84] High-dose fluconazole, alone or in combination with amphotericin B, in non-immunocompromised patients with candidemia demonstrated no antagonism and a trend toward improved success and more rapid clearance of *Candida* from the bloodstream.[47]

ABBREVIATIONS

AIDS: acquired immunodeficiency syndrome
ACTG: AIDS Clinical Trials Group
ATCC: American Type Culture Collection
ABCD: amphotericin B colloid dispersion
ABLC: amphotericin B lipid complex

CHAPTER 131

Infections in Immunocompromised Patients

DOUGLAS N. FISH

KEY CONCEPTS

1. An *immunocompromised host* is a patient with defects in host defenses that predispose to infection. Risk factors include neutropenia, immune system defects (from disease or immunosuppressive drug therapy), compromise of natural host defenses, environmental contamination, and changes in normal flora of the host.

2. Immunocompromised patients are at high risk for a variety of bacterial, fungal, viral, and protozoal infections. Bacterial infections caused by gram-positive cocci (staphylococci and streptococci) occur most frequently, followed by gram-negative bacterial infections caused by Enterobacteriaceae and *Pseudomonas aeruginosa.* Fungal infections caused by *Candida* and *Aspergillus*, as well as certain viral infections (herpes simplex virus, Cytomegalovirus), are also important causes of morbidity and mortality.

3. Risk of infection in neutropenic patients is associated with both the severity and duration of neutropenia. Patients with severe neutropenia (ANC <500 cells/mm^3) for greater than 7 to 10 days are considered to be at high risk of infection.

4. Fever (single oral temperature of ≥38.3°C [101°F], or a temperature of ≥38°C [100.4°F] for ≥1 hour) is the most important clinical finding in neutropenic patients and is usually the stimulus for further diagnostic workup and initiation of antimicrobial treatment. Infection should be considered as the cause of fever until proven otherwise. Usual signs and symptoms of infection may be altered or absent in neutropenic patients. Appropriate empiric broad-spectrum antimicrobial therapy must be rapidly instituted to prevent excessive morbidity and mortality.

5. Empiric antimicrobial regimens for neutropenic infections should take into account patients' individual risk factors, as well as institutional infection and susceptibility patterns. The significant morbidity and mortality associated with gram-negative infections require that initial empiric regimens for treatment of febrile neutropenia have good activity against *P. aeruginosa* and Enterobacteriaceae. Inpatient parenteral regimens most commonly recommended for initial treatment include monotherapy with an antipseudomonal cephalosporin or carbapenem, or a combination regimen consisting of an antipseudomonal cephalosporin or carbapenem, plus an aminoglycoside. Low-risk patients may be successfully treated with oral antibiotics (ciprofloxacin plus amoxicillin/clavulanate), with the treatment setting determined by the patient's clinical status.

6. Neutropenic patients who remain febrile after 3 to 5 days of initial antimicrobial therapy should be reevaluated to determine whether treatment modifications are necessary. Common regimen modifications include addition of vancomycin (if not already administered) and antifungal therapy (amphotericin B or fluconazole). Therapy should be directed at causative organisms, if identified, but broad-spectrum regimens should be maintained during neutropenia.

7. The optimal duration of therapy for febrile neutropenia is controversial. The decision to discontinue antimicrobials is based on resolution of neutropenia, defervescence, culture results, and clinical stability of the patient.

8. Prophylactic antimicrobials are administered to cancer patients expected to experience prolonged neutropenia, as well as to both hematopoietic stem cell and solid-organ transplant recipients. Prophylactic regimens may include antibacterial, antifungal, antiviral, or antiprotozoal agents, or a combination of these, selected according to risk of infection with specific pathogens. Optimal prophylactic regimens should take into account individual patient risk for infection and institutional infection and susceptibility patterns.

9. Patients undergoing hematopoietic stem cell transplantation are at an extremely high risk of infection because of prolonged neutropenia following intensive chemotherapy ± irradiation, while solid-organ transplant recipients are at high risk because of prolonged administration of immunosuppressive drugs. Fungal *(Aspergillus)* and viral (Cytomegalovirus) infections are particularly troublesome in these populations, and prophylactic regimens directed against these pathogens are commonly used. When documented, these infections must be treated aggressively in order to optimize patient outcomes. Nevertheless, mortality rates are often high despite appropriate and aggressive antimicrobial therapy.

10. Immunocompromised patients must be continuously assessed for evidence of infection and response to antimicrobial therapy. Because a large number of antimicrobials may potentially be used, the occurrence of drug-related adverse effects must also be carefully assessed. Efforts should be directed at designing cost-effective treatment strategies that promote optimal patient outcomes.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

An immunocompromised host is a patient with intrinsic or acquired defects in host immune defenses that predispose to infection. Advances in modern medicine have created more immunocompromised hosts than ever before. Historically, many of these patients died of their underlying diseases. Dramatic improvements in survival have been achieved by more aggressive therapy of underlying diseases and improved supportive care. However, because such aggressive therapy often renders patients profoundly immunosuppressed for long periods, opportunistic infections remain important causes of morbidity and mortality. This chapter focuses on risk factors for infection, common pathogens and infection sites, and prevention and management of suspected or documented infections in cancer patients (including hematopoietic stem cell transplantation [HSCT] patients) and solid-organ transplant recipients. Chapter 134 discusses infectious complications associated with human immunodeficiency virus (HIV) infection.

RISK FACTORS FOR INFECTION/EPIDEMIOLOGY

Many factors influence the degree of immunosuppression and also influence the epidemiology of the associated infections.

NEUTROPENIA

1 2 3 Neutropenia is defined as an abnormally reduced number of neutrophils circulating in peripheral blood. Although exact definitions of neutropenia can vary, an absolute neutrophil count (ANC) of less than 1,000 cells/mm^3 indicates a reduction sufficient to predispose patients to infection.[1] ANC is the sum of the absolute numbers of both mature neutrophils (polymorphonuclear cells [PMNs], also called *polys* or *segs*) and immature neutrophils (*bands*). The absolute number of PMNs and bands is determined by dividing the total percentage of these cells (obtained from the white blood cell [WBC] differential) by 100 and then multiplying the quotient obtained by the total number of WBCs.

The degree or severity of neutropenia, rate of neutrophil decline, and duration of neutropenia are important risk factors for infection.[1–5] All neutropenic patients are considered to be at risk for infection, but those with ANC less than 500 cells/mm^3 are at greater risk than those with ANCs of 500 to 1,000 cells/mm^3. Most treatment guidelines use ANC less than 500 cells/mm^3 as the critical value in making therapeutic decisions regarding the management of suspected or documented infections.[1–5] Risk of infection and death are greatest among patients with less than 100 neutrophils/mm^3 ("profound neutropenia").[1,2] In patients with chemotherapy-induced neutropenia, the risk of infection is also increased according to the rapidity of ANC decline. Infection risk also increases as the duration of neutropenia increases; patients with severe neutropenia of more than 7 to 10 days' duration are considered to be at especially high risk for serious infections.[3] The duration of chemotherapy-induced neutropenia varies considerably among subsets of cancer patients according to the specific chemotherapeutic agents used and the intensity of treatment. Patients undergoing HSCT may have no detectable granulocytes in peripheral blood for up to 3 to 4 weeks and are at particular risk for severe infections with a variety of pathogens.[6]

Bacteria and fungi commonly cause infections in neutropenic patients. Gram-positive cocci (*Staphylococcus aureus*, *Staphylococcus epidermidis*, streptococci, and enterococci) have emerged as the most common cause of acute bacterial infections among neutropenic patients. Gram-negative bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*) traditionally were the most common causes of bacterial infection and remain frequent pathogens.[4,7–9] Although not now as common as gram-positive bacteria, the incidence of gram-negative infections may again be increasing.[3,8] Gram-negative infections are associated with significant morbidity and mortality, in large part due to increasing antibiotic resistance.[7–9] Patients who are neutropenic for extended periods and who receive broad-spectrum antibiotics are at high risk for fungal infections, usually due to *Candida* or *Aspergillus* spp.[2,3,10,11] Viral infections, although not as common as bacterial and fungal infections, also may cause severe infection in neutropenic patients.[2,3,5,12] Successful treatment of infections in neutropenic patients depends on resolution of neutropenia.[1–3,5]

Although not readily quantifiable, abnormalities may exist in granulocyte function as well as in cell numbers. Defects in phagocyte function may be caused by underlying disease (e.g., leukemia) or its treatment (e.g., corticosteroids, antineoplastic agents, and radiation).[3,13,14]

IMMUNE SYSTEM DEFECTS

In addition to neutropenia, defects in T lymphocyte and macrophage function (cell-mediated immunity), B-cell function (humoral immunity), or both predispose patients to infection. Cellular immune dysfunction is the result of underlying disease or immunosuppressive drug therapy; these defects result in a reduced ability of the host to defend against intracellular pathogens. Patients with Hodgkin's disease and transplant patients receiving a wide variety of immunosuppressive drugs, such as cyclosporine, tacrolimus, sirolimus, mycophenolate, corticosteroids, azathioprine, and antineoplastic agents, are at risk for a variety of bacterial, fungal, viral, and protozoal infections (Table 131–1). Although some of these pathogens are associated with asymptomatic or mild disease in normal hosts, they may cause disseminated, life-threatening infections in immunocompromised hosts.

Underlying disease also frequently causes defects in humoral immune function. Patients with multiple myeloma and chronic lymphocytic leukemia have progressive hypogammaglobulinemia that results in defective humoral immunity. Splenectomy performed as a part of the staging process for Hodgkin's disease places patients at risk for infectious complications. Disease states with humoral immune dysfunction predispose the patient to serious, life-threatening infection with encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*.

DESTRUCTION OF PROTECTIVE BARRIERS

Loss of protective barriers is a major factor predisposing immunocompromised patients to infection. Damage to skin and mucous membranes by surgery, venipuncture, intravenous (IV) and urinary catheters, radiation, and chemotherapy disrupts natural host defense systems, leaving patients at high risk for infection. Chemotherapy-induced mucositis may erode mucous membranes of the oropharynx and gastrointestinal (GI) tract and establish a portal for subsequent infection by bacteria, herpes simplex virus (HSV), and *Candida*.[3,15] Medical and surgical procedures, such as transplant surgery, indwelling IV catheter placement, bone marrow aspiration, biopsies, and endoscopy, further damage the integument and predispose patients to infection. Infections resulting from disruption of protective barriers usually are a result of skin flora, such as *S. aureus*, *S. epidermidis*, and various streptococci.[1,3,5,13,15]

ENVIRONMENTAL CONTAMINATION/ ALTERATION OF MICROBIAL FLORA

Infections in immunocompromised patients are caused by organisms either colonizing the host or acquired from the environment.

TABLE 131-1 Risk Factors and Common Pathogens in Immunocompromised Patients

Risk Factor	Patient Conditions	Common Pathogens
Neutropenia	Acute leukemia Chemotherapy	Bacteria: *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, streptococci, enterococci Fungi: *Candida*, *Aspergillus*, *Zygomycetes* Viruses: Herpes simplex
Impaired cell-mediated immunity	Lymphoma Immunosuppressive therapy (steroids, cyclosporine, chemotherapy)	Bacteria: *Listeria*, *Nocardia*, *Legionella*, Mycobacteria Fungi: *Cryptococcus neoformans*, *Candida*, *Aspergillus*, *Histoplasma capsulatum* Viruses: Cytomegalovirus, varicella-zoster, herpes simplex Protozoal: *Pneumocystis jiroveci*
Impaired humoral immunity	Multiple myeloma Chronic lymphocytic leukemia Splenectomy Immunosuppressive therapy (steroids, chemotherapy)	Bacteria: *S. pneumoniae*, *H. influenzae*, *N. meningitidis*
Loss of protective skin barriers	Venipuncture, bone marrow aspiration, urinary catheterization, vascular access devices, radiation, biopsies	Bacteria: *S. aureus*, *S. epidermidis*, *Bacillus* spp, *Corynebacterium jeikeium* Fungi: *Candida*
Mucous membranes	Respiratory support equipment, endoscopy, chemotherapy, radiation	Bacteria: *S. aureus*, *S. epidermidis*, streptococci, Enterobacteriaceae, *P. aeruginosa*, *Bacteroides* spp Fungi: *Candida* Viruses: Herpes simplex
Surgery	Solid-organ transplantation	Bacteria: *S. aureus*, *S. epidermidis*, Enterobacteriaceae, *P. aeruginosa*, *Bacteroides* spp Fungi: *Candida* Viruses: Herpes simplex
Alteration of normal microbial flora	Antimicrobial therapy Chemotherapy Hospital environment	Bacteria: Enterobacteriaceae, *P. aeruginosa*, *Legionella*, *S. aureus*, *S. epidermidis* Fungi: *Candida*, *Aspergillus*

Microorganisms may be transferred easily from patient to patient on the hands of hospital personnel unless strict infection control guidelines are followed. Contaminated equipment, such as nebulizers or ventilators, and contaminated water supplies have been responsible for outbreaks of *P. aeruginosa* and *Legionella pneumophila* infections, respectively. Foods, such as fruits and green leafy vegetables, which often are colonized with gram-negative bacteria and fungi, are sources of microbial contamination in immunocompromised hosts.[3,16]

Most infections in cancer patients are caused by organisms colonizing body sites, such as the skin, oropharynx, and GI tract.[1,3,15,16] Approximately 80% of infecting bacterial pathogens are from the patient's own endogenous flora.[1,3] The GI tract is the most common site from which infections in immunocompromised hosts originate. Periodontitis, pharyngitis, esophagitis, colitis, perirectal cellulitis, and bacteremias are caused predominantly by normal flora of the gut; bloodstream infections are thought to arise from microbial translocation across injured GI mucosa.[1,15,16] Normal flora may be significantly disrupted and altered; oropharyngeal flora rapidly change to primarily gram-negative bacilli in hospitalized patients. Many cancer patients may already be colonized with gram-negative bacilli on admission as a result of frequent prior hospitalizations and clinic visits. In hospitalized cancer patients, however, up to 50% of infections are caused by colonizing organisms acquired after admission.[1,3]

Although hospitalization and severity of illness are important risk factors for colonization by gram-negative bacilli, administration of broad-spectrum antimicrobial agents has the greatest impact on flora of immunocompromised hosts. Use of these agents disrupts GI tract flora and predisposes patients to infection with more virulent pathogens. Antineoplastic drugs (e.g., cyclophosphamide, doxorubicin, and fluorouracil) and acid-suppressive therapy (e.g., H_2-receptor antagonists, proton pump inhibitors, and antacids) also may result in changes in GI flora and possibly predispose patients to infection.[1,3,16]

Numerous factors, such as underlying disease, immunosuppressive drug therapy, and antimicrobial administration, determine the immunocompromised host's risk of developing infection. Several risk factors are present concomitantly in many patients (see Table 131–1).

ETIOLOGY OF INFECTIONS IN NEUTROPENIC CANCER PATIENTS

2 Infection remains a significant cause of morbidity and mortality in neutropenic cancer patients. More than 50% of febrile neutropenic patients have an established or occult infection.[1,5] Patients with profound neutropenia are at greatest risk for systemic infection, with at least 20% of these individuals developing bacteremia. Areas of impaired or damaged host defenses, such as the oropharynx, lungs, skin, sinuses, and GI tract, are common sites of infection. These local infections may progress to cause systemic infection and bacteremia.[15] Febrile episodes in neutropenic cancer patients can be attributed to microbiologically documented infection in approximately 30% to 40% of cases, about half of which are due to bacteremia. Further, infections can be documented clinically (but not microbiologically) in another 30% to 40% of patients, with the remaining 30% of patients manifesting infection only by fever.[3,4,8,13]

Table 131–1 lists organisms commonly infecting immunocompromised patients. Approximately 45% to 70% of bacteremic episodes in cancer patients are the result of gram-positive organisms compared with less than 30% of episodes documented during the 1970s and 1980s.[1,4,7,13,17,18] This shift is attributed to the frequent use

of indwelling central and peripheral IV catheters, frequent use of broad-spectrum antibiotics with excellent gram-negative activity but relatively poor gram-positive coverage, higher rates of mucositis caused by aggressive cancer treatments, and prophylaxis with trimethoprim–sulfamethoxazole or quinolones.[1,4,7,13] *S. aureus* and coagulase-negative staphylococci (especially *S. epidermidis*) account for most infections, but *Bacillus* spp and *Corynebacterium jeikeium* are also important pathogens.[1,5,13,18] Data from the U.S. Centers for Disease Control and Prevention's (CDC) National Nosocomial Infection Surveillance System (NNIS) indicate increasing rates of infection due to methicillin-resistant *Staphylococcus aureus* (MRSA) in the hospital setting.[19] Resistance is also common in community-acquired staphylococcal infections.[20,21] Viridans streptococci, which may be resistant to β-lactams, also have emerged as important pathogens, particularly in patients with chemotherapy-induced mucositis of the oropharynx.[4,13,22] Enterococci, including vancomycin-resistant strains, also may be problematic in many institutions.[2,7] Bacteremia caused by vancomycin-resistant enterococci (VRE) in neutropenic patients is associated with a mortality rate exceeding 70%.[4,23]

Gram-positive infections do not always cause immediately life-threatening infections and are associated with somewhat lower mortality rates (approximately 5%–10%) compared with gram-negative infections.[1,13,18] However, increasing rates of antibiotic resistance have made treatment of gram-positive infections in immunocompromised patients more challenging.[7,13] MRSA infections are associated with increased morbidity and mortality and hospital costs compared with susceptible organisms.[24] Methicillin resistance among coagulase-negative staphylococci, which may cause 40% to 80% of infections in certain populations, is very common (70%–90% of isolates).[7,25] Organisms that are intrinsically resistant to vancomycin (e.g., *Lactobacillus*) are increasing in importance.[7] Thus, prevention and timely diagnosis and treatment of gram-positive infections are clearly of great importance in the management of neutropenic cancer patients.

Gram-negative infections remain important causes of morbidity and mortality (approximately 20%) in immunocompromised cancer patients.[13,18] However, the relative frequency of infection owing to specific pathogens has been shifting among gram-negative infections. *E. coli* and *Klebsiella* spp remain the most common isolates at many centers.[18] Strains of *Klebsiella* spp producing plasmid-mediated extended-spectrum β-lactamases that hydrolyze extended-spectrum cephalosporins have emerged and are cause for concern.[1,7] The frequency of infections resulting from other gram-negative organisms, such as *Enterobacter*, *Serratia*, and *Citrobacter*, has been increasing.[7] *Enterobacter* spp are also important causes of bacteremias; use of broad-spectrum antibiotics, particularly third-generation cephalosporins, is thought to have played a major role in this trend. Infections with *Enterobacter*, *Serratia*, and *Citrobacter* may be difficult to treat because of the ease of β-lactamase induction and the more frequent development of resistance to multiple antibiotics.[3,7,13]

P. aeruginosa has long been an important pathogen in cancer patients. *P. aeruginosa* infection rates are decreasing in patients with solid tumors but not in patients with hematologic malignancies.[4,7] Infections caused by *P. aeruginosa* are associated with significant morbidity and mortality in neutropenic patients, with mortality rates of 31% to 75% reported.[13,18] The frequency of infection caused by difficult-to-treat organisms such as *Stenotrophomonas maltophilia* and *Burkholderia cepacia* appears to be increasing at many centers, probably because of selective pressures of broad-spectrum antimicrobial use.[4,13] As with gram-positive organisms, antibiotic resistance among gram-negative organisms has continued to increase at alarming rates and has made appropriate antibiotic selection for treatment of febrile neutropenia more difficult.[1,7,19] Although the GI tract is a common site of bacterial infection, severe infections caused by anaerobic organisms are relatively infrequent. Anaerobes are found most frequently in mixed infections, such as perirectal cellulitis and mucositis-associated oropharyngeal infections.[13]

In addition to bacterial infections, neutropenic cancer patients are at risk for invasive fungal infections. Patients with extended periods of profound neutropenia who have been receiving broad-spectrum antibiotics, corticosteroids, or both are at the highest risk for invasive fungal infection. Up to one third of febrile neutropenic patients who do not respond to 1 week of broad-spectrum antibiotic therapy will have a systemic fungal infection.[1,13] Large autopsy studies have documented that up to 40% of patients with hematologic malignancies had deep fungal infections, fully 75% of which were undiagnosed prior to death. Causative pathogens were usually either *Candida* spp (35%) or *Aspergillus* spp (55%).[26]

Candida albicans is the most common fungal pathogen in neutropenic cancer patients.[4,13,27] However, non-*albicans* species of *Candida* including *C. glabrata*, *C. tropicalis*, *C. parapsilosis*, and *C. krusei* are being isolated with increasing frequency and are more common than *C. albicans* infections in some studies.[11,27] Increased infections caused by pathogens such as *Trichosporon* spp, *Fusarium* spp, and *Curvularia* have also been reported.[27–31] The shift toward more frequent infection with non-*albicans Candida* is important because of significantly decreased rates of susceptibility among many of these strains.[32] Because *Candida* spp are normal flora, alteration of body host defenses is an important risk factor for the development of these infections. Oral thrush is the most common clinical manifestation of fungal infection. Mucous membranes damaged from chemotherapy and radiation serve as areas of *Candida* surface colonization and subsequent entry into the bloodstream; disease then may disseminate throughout the body. Organs such as the liver, spleen, kidney, and lungs are commonly involved in disseminated disease.[14,26,28] Hepatosplenic candidiasis is a particularly important infection in patients with hematologic malignancies.[3,26,28] Diagnosis of candidal infections is difficult and often requires invasive tissue sampling.[6] Overall mortality attributed to candidal infections in patients with invasive candidiasis is as high as 35% to 50%.[4,11,27]

Invasive infections caused by *Aspergillus* spp are a serious complication of neutropenia, with mortality approaching 80% in patients with prolonged neutropenia and/or patients undergoing allogeneic HSCT.[4,13] These infections are particularly prevalent in patients with hematologic malignancies and in patients undergoing HSCT.[4,28,31,33] Infections resulting from *Aspergillus* spp (including *A. fumigatus*, *A. terreus*, *A. flavus*, and *A. niger*) usually are acquired via inhalation of airborne spores. After colonizing the lungs, *Aspergillus* invades the lung parenchyma and pulmonary vessels, resulting in hemorrhage, pulmonary infarcts, and a high mortality rate. Invasive pulmonary disease is the dominant manifestation of infection in patients with neutropenia. However, *Aspergillus* spp also may cause other infections, including sinusitis, cutaneous infection, and disseminated disease involving multiple organs, including the central nervous system (CNS).[33] Prolonged neutropenia is the primary risk factor for invasive pulmonary aspergillosis in neutropenic patients with acute leukemia; use of corticosteroids also may predispose patients to disease.[33] Invasive aspergillosis should be suspected in neutropenic cancer patients colonized with *Aspergillus* (in sputum and/or nasal cultures) who remain persistently febrile despite at least 1 week of broad-spectrum antibiotic therapy.[1,33]

Chemotherapy-induced mucous membrane damage may predispose neutropenic cancer patients to the reactivation of HSV, manifesting as gingivostomatitis or recurrent genital infections. Untreated oropharyngeal HSV infections may spread to involve the esophagus and often coexist with candidal infections. Clinical disease resulting from HSV occurs most often in patients with serologic evidence (e.g., serum antibodies to HSV) of prior infection. Both HSV-seropositive HSCT patients and HSV-seropositive

leukemics receiving intensive chemotherapy are at high risk for recurrent HSV disease during periods of immunosuppression.[3,4,6,13]

Pneumocystis jiroveci and *Toxoplasma gondii* are the most common parasitic pathogens found in immunocompromised cancer patients. Patients with hematologic malignancies (i.e., acute lymphocytic leukemia, lymphoma, and Hodgkin's disease) and those receiving high-dose corticosteroids as part of chemotherapy regimens are at the greatest risk of infection.[3,4,6,13] Routine use of trimethoprim–sulfamethoxazole prophylaxis has reduced substantially the incidence of these infections.[1,6]

Because the majority of infecting organisms in cancer patients are from the host's own flora, some centers have used routine surveillance cultures in an attempt to prospectively identify causes of fever and suspected infection. In a typical surveillance culture program, cultures of the nose, mouth, axillae, and perirectal area are performed twice weekly, and culture results are correlated with the clinical status of the patient. Because these cultures are costly and have low diagnostic yield, the utility of surveillance culture programs is believed to be limited.[1] However, surveillance cultures are useful as research tools and in certain clinical situations, including patients with prolonged profound neutropenia and in institutions that have high rates of antimicrobial resistance or have problems with virulent pathogens such as *P. aeruginosa* or *Aspergillus* spp. Surveillance cultures should be limited to the anterior nares for detecting colonization with MRSA, *Aspergillus*, and penicillin-resistant pneumococci and to the rectum for detecting *P. aeruginosa*, multiple-antibiotic-resistant gram-negative rods, and VRE.[1,13]

Knowledge of infection rates and local susceptibility patterns is essential for guiding optimal management of febrile neutropenia. These parameters must be monitored closely because the spectrum of infectious complications is related to multiple factors, including cancer chemotherapy regimens and antimicrobial therapy used for treatment and prophylaxis.

CLINICAL PRESENTATION

4 The most important clinical finding in the neutropenic cancer patient is fever. Because of the potential for significant morbidity and mortality associated with infection in these patients, fever should be considered to be the result of infection until proved otherwise.[1–3,8,13] At the appearance of fever, the patient should be evaluated carefully for other signs and symptoms of infection.

CLINICAL PRESENTATION OF FEBRILE NEUTROPENIA[1,3,4,6,12]

General

- Because neutropenic cancer patients are at high risk for serious infections, frequent (at least daily) careful clinical assessments must be performed to search for possible evidence of infection.
- Physical assessment should include examination of all common sites of infection, including mouth/pharynx, nose and sinuses, respiratory tract, GI tract, urinary tract, skin, soft tissues, perineum, and intravascular catheter insertion sites.

Symptoms

- Usual signs and symptoms of infection may be absent or altered in neutropenic patients owing to low numbers of leukocytes and an inability to mount an inflammatory response (e.g., no infiltrate on chest x-ray film, urinary tract infection without pyuria).
- Pain may be present at the infection site(s).

Signs

- Fever in this setting is defined as a single oral temperature ≥38.3°C (≥101°F) in the absence of other causes or temperature ≥38°C (≥100.4°F) for 1 hour or more. Other causes of fever unrelated to infection in this patient population include reactions to blood products, chemotherapeutic agents (and other drugs, including biologics), cell lysis, and underlying malignancy.
- Usual signs of infection may be absent or altered; patients with bacteremia commonly exhibit no signs of infection other than fever.

Laboratory Tests

- Neutropenia (ANC ≤1,000 cells/mm^3).
- Blood cultures (two or more sets, including vascular access devices) for bacteria and fungi; cultures of other suspected infection sites (infection can be documented microbiologically in only about 30% of cases, about half of which are due to bacteremia).
- Other cultures should be obtained as indicated clinically according to the presence of signs or symptoms.
- Recent surveillance cultures (nasal, rectal) should be reviewed, if available.
- Complete blood count and blood chemistries should be obtained frequently to monitor neutropenia, plan supportive care, guide drug dosing, and assess patient's overall status.

Other Diagnostic Tests

- Chest x-ray film
- Aspiration, biopsy of skin lesions
- Other diagnostic tests as indicated clinically on the basis of physical examination and other assessments

TREATMENT

Infections in Cancer Patients

Management of patients with febrile neutropenia, including both treatment and prophylaxis of infectious complications, can be extremely challenging. Although published guidelines are available, the most optimal clinical management of these patients remains unclear in many aspects.

FEBRILE EPISODES IN NEUTROPENIC CANCER PATIENTS

4 5 The goals of antimicrobial therapy in neutropenic patients (including HSCT recipients) are (a) to protect the neutropenic patient from early death caused by undiagnosed infection; (b) to prevent breakthrough bacterial, fungal, viral, and protozoal infections during periods of neutropenia; and (c) to treat established infections effectively, all aimed at reducing patient morbidity and mortality and allowing for administration of optimal antineoplastic therapy. All these goals must be achieved at the lowest possible toxicity and cost.

Approach to Treatment

General guidelines for management of febrile episodes and documented infections in neutropenic patients are shown in Figure 131–1 (from the Infectious Diseases Society of America [IDSA],

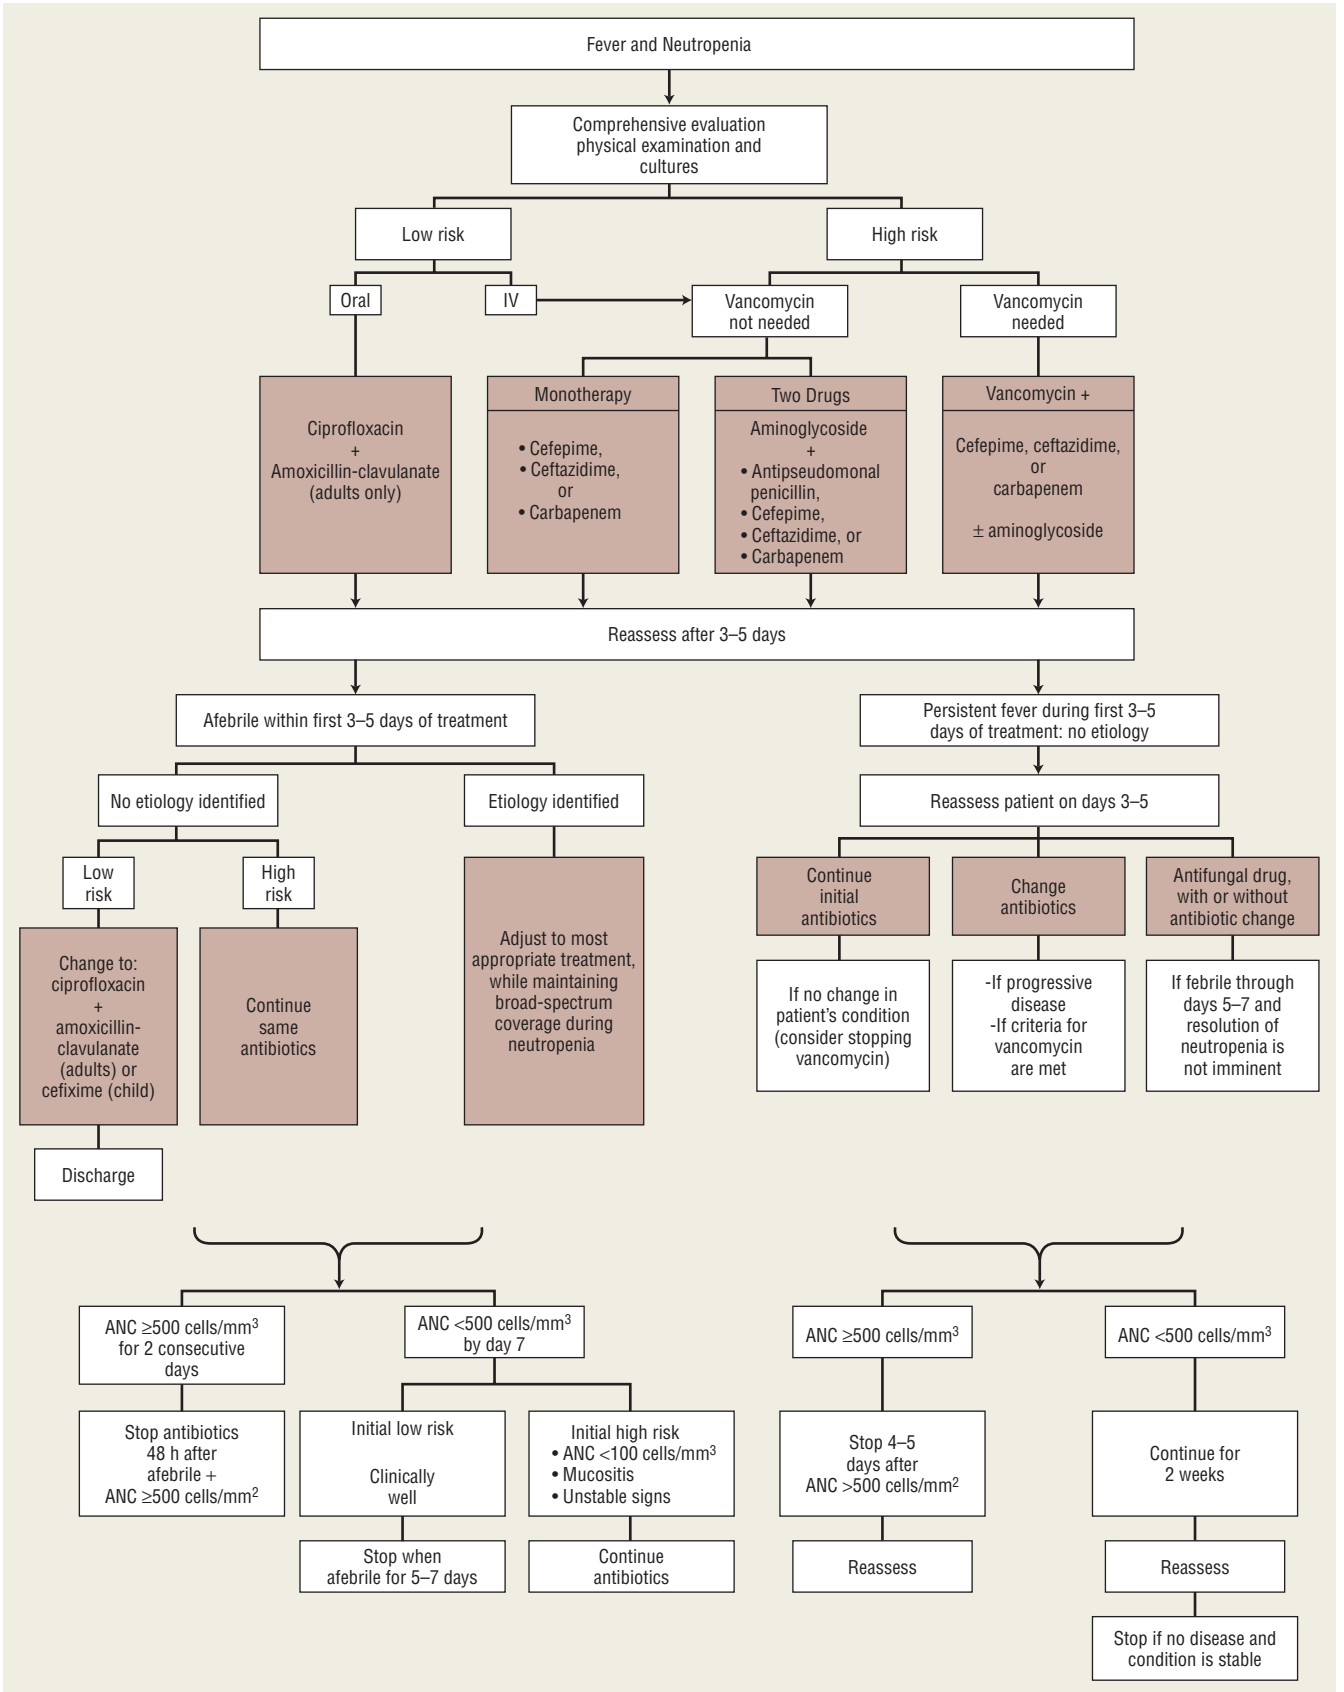

FIGURE 131-1. Management of febrile episodes in neutropenic cancer patients. (ANC, absolute neutrophil count; carbapenem, imipenem–cilastatin, meropenem.) *(Adapted from Hughes WT, Armstrong D, Bodey GP, et al. 2002 guidelines for the use of antimicrobial agents in neutropenic patients with cancer. Clin Infect Dis 2002;34:730–751. © 2002 by the Infectious Diseases Society of America. Used with permission of the University of Chicago Press.)*

TABLE 131-2 Summary of Evidence-Based Recommendations for Management of Febrile Episodes in Neutropenic Patients

Recommendations	Recommendation Grades[a]
Use of oral antibiotics for outpatient management	
Oral antibiotics are feasible for treatment of carefully selected patients at low risk for complications.	A-1
Use of monotherapy	
Monotherapy with appropriate antibiotics is as effective as combination regimens for initial empirical treatment of febrile neutropenic episodes.	A-1
Route of antibiotic administration for initial treatment	
Patients at high risk for serious life-threatening infections must be initially treated with intravenous antibiotics. Patients at low risk can be treated with either intravenous or oral drugs (see text for risk stratification criteria).	A-2
Management of patients who become afebrile	
Patients who become afebrile within 3–5 days of beginning initial empirical antibiotic therapy and in whom specific organisms have been identified should be treated for ≥7 days (until cultures are negative and patient has clinically recovered). Low-risk patients in whom no organism is identified can be switched to oral antibiotics if desired, whereas patients originally classified as high risk should continue on intravenous antibiotics.	B-2
Management of patients with persistent fever during first 3–5 days of treatment	
In patients initially receiving monotherapy or a two-drug regimen *not* including vancomycin, addition of vancomycin can be considered if any criteria for use of vancomycin are present (see text for specific criteria).	C-3
In patients *already* receiving vancomycin as part of the initial empirical regimen, withdrawal of vancomycin should be considered in the absence of a documented pathogen requiring continued therapy. Other initial antibiotics can be continued if the disease has not progressed, or switched to oral therapy if the patient was classified as low risk even in the presence of continued fever.	C-3
Management of patients with fever persisting for more than three days after initial treatment	
Reassess patient after 3 days of treatment. If still febrile by day 5, then continue the same antibiotics if clinically stable; change antibiotics if any evidence of disease progression or antibiotic toxicities; or add an antifungal drug if the duration of neutropenia is expected to be more than 5–7 additional days.	B-2
Continuation of antibiotics in afebrile patients with no identified infection	
Antibiotic therapy can be discontinued after 3 days of treatment if patient is afebrile for ≥48 hours and absolute neutrophil count (ANC) is ≥500 cells/mm^3 for 2 consecutive days.	C-3
If patient remains neutropenic, continue intravenous or oral antibiotics.	B-2
Antibiotics should be continued in patients with profound neutropenia (ANC <100 cells/mm^3), mucous membrane lesions of mouth or gastrointestinal tract, unstable vital signs, or other identified risk factors.	C-3
Antibiotics can be stopped after 2 weeks in patients with prolonged neutropenia of unclear continued duration, no identified site of infection, and who can be closely observed.	C-3
Alternatively, antibiotics can be discontinued after 4 days if no infection is documented and the patient shows no response to therapy.	C-3
Management of Fungal infections	
Suspected candidiasis:	
Lipid-formulated amphotericin B or caspofungin	A-1
Voriconazole	B-1
Fluconazole or itraconazole	B-1
Candidemia:	
An echinocandin or lipid-formulated ampohotericin B	A-2
Fluconazole or voriconazole	B-3
Granulocyte transfusions	
There are no specific indications for routine use of granulocyte transfusions.	C-2
Colony-stimulating factors	
Colony-stimulating factors are not indicated for routine treatment of neutropenia in either febrile or afebrile patients.	D-2
Antimicrobial prophylaxis in neutropenic patients	
Prophylaxis with trimethoprim-sulfamethoxazole should be administered to all patients at risk for *Pneumocystis jiroveci* pneumonia, regardless of whether they are neutropenic.	A-1
Prophylaxis with fluconazole, posaconazole, or caspofungin is recommended with induction chemotherapy and continued for duration of neutropenia; itraconzole is an effective alternative agent.	A-1 for all agents except caspofungin (B-2)
In HSCT, prophylaxis with fluconazole, posaconazole, or micafungin is recommended during the period of risk of neutropenia.	A-1
In HSCT patients with graft-versus-host disease, or neutropenic patients with hematologic malignancies, prophylaxis with posaconazole is recommended for prevention of invasive fungal infections.	A-1

[a]Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation for use, respectively; D = moderate evidence to support a recommendation against use.
Quality of evidence: 1 = evidence from ≥1 properly randomized, controlled trial; 2 = evidence from ≥1 well-designed clinical trial without randomization, from cohort or case-control analytic studies, from multiple time series, or from dramatic results from uncontrolled experiments; 3 = evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.
Data from references 1, 5, 27, and 33.

revised in 2002).[1] Updated guidelines from the IDSA are expected in 2010. Although many controversies remain regarding optimal management of these patients, the IDSA guidelines and those of other expert panels, such as the National Comprehensive Cancer Network (NCCN),[5] offer an evidence-based consensus approach to the management of febrile neutropenia. Selected specific recommendations as discussed in the following sections of this chapter, and their associated evidence-based rankings are summarized in Table 131–2.

Fever in the neutropenic cancer patient is considered to be caused by infection until proved otherwise. High-dose broad-spectrum bactericidal, usually parenteral, empirical antibiotic therapy should

TABLE 131-3 Risk-Based Therapy for Febrile Patients with Neutropenia

Risk Group	Patient Characteristics	Treatment Strategies
High risk	*Neutropenia:* Severe (absolute neutrophil count <100/mm³) and/or prolonged (≥14 days) *Malignancy/treatment:* Hematologic malignancy or allogeneic HSCT *Comorbidities:* Substantial comorbidity; poor performance status *Clinical status:* Clinical or hemodynamic instability (e.g., shock) and/or complex infection (e.g., pneumonia, bacteremia) *Response to initial therapy:* Slow response	*Therapy/setting:* Broad-spectrum, parenteral (IV) therapy, hospital-based for duration of febrile neutropenia
Moderate risk	*Neutropenia:* Moderate duration (7–14 days) *Malignancy/treatment:* Solid tumor treated with autologous HSCT *Comorbidities:* Minimal medical comorbidity *Clinical status:* Clinically stable *Response to initial therapy:* Favorable (e.g., early defervescence)	*Therapy/setting:* Initial parenteral, hospital-based therapy, followed by early discharge on a parenteral or oral regimen (sequential)
Low risk	*Neutropenia:* Short duration (≤7 days) *Malignancy/treatment:* Solid tumor treated with conventional chemotherapy *Comorbidities:* None *Clinical status:* Clinically stable at onset of fever; no identified focus of infection, or simple infection (e.g., urinary tract infection)	*Therapy/setting:* Broad-spectrum outpatient therapy (parenteral, sequential, or oral) for the entire episode

HSCT, hematopoietic stem cell transplantation.

Data from Hughes et al.,[1] Ellis,[4] National Comprehensive Cancer Network Practice Guidelines,[5] Antoniadou and Giamarellou,[13] Kern,[35] Moores,[36] and Carstensen and Sorensen.[37]

thus be initiated at the onset of fever or at the first signs or symptoms of infection. Withholding antibiotic therapy until an organism is isolated results in unacceptably high mortality rates. Undiagnosed infection in immunocompromised patients can rapidly disseminate and result in death if left untreated or if treated improperly. Failure to initiate appropriate antibiotic therapy for *P. aeruginosa* bacteremia at the onset of fever in neutropenic cancer patients resulted in mortality rates of 15% and 70% within 12 and 48 hours, respectively.[1] Empirical antibiotic therapy is 70% to 90% effective at reducing early morbidity and mortality.[13] Therapy must be appropriate and initiated promptly. Antimicrobial therapy also should be initiated promptly in afebrile cancer patients with clinical signs and symptoms of infection.

When designing optimal empirical antibiotic regimens, clinicians must consider infection patterns and antimicrobial susceptibility trends in their respective institutions. Patient factors such as risk for infection, drug allergies, concomitant nephrotoxins, and previous antimicrobial exposure (including prophylaxis) must be considered.[1,4,5] Assessment of the patient's risk of infection will help determine the appropriate route and setting for antibiotic administration. Patients with neutropenia can be divided into low-, moderate-, and high-risk groups based on the projected duration of neutropenia and other risk factors for serious infection (Table 131–3).[3,4,9,11,13] Patients with neutropenia of short duration (≤7 days), clinically stable, and without significant co-morbidities are often considered to be at relatively low risk of severe infection. Patients with neutropenia lasting 7 to 14 days are considered to be at moderate risk for severe infection. High-risk patients are those with profound neutropenia, neutropenia for 14 or more days, and/or clinically unstable with systemic signs of infection; these patients are at increased risk for severe bacterial infection as well as from fungal, viral, and parasitic infection.[1,13]

Oral empirical antimicrobial therapy may be appropriate for certain low-risk patients, such as those without a focus of infection and no systemic signs of infection other than fever.[1,5,34–37] The patient's overall clinical condition and other risk factors for infection determine whether oral therapy is administered on an inpatient or outpatient basis. If therapy is administered on an outpatient basis, the patient must be compliant with treatment and have prompt access to medical care around the clock, should his or her condition worsen. Patients considered at moderate risk of infection should receive at least the first few days of therapy administered parenterally in the hospital setting.[1,4,13] High-risk patients generally are treated with hospital-based parenteral therapy for the entire course of their treatment.

The optimal antibiotic regimen for empirical therapy in febrile neutropenic cancer patients remains controversial, but it is clear that no single regimen can be recommended for all patients. Because of their frequency and relative pathogenicity, *P. aeruginosa* and other gram-negative bacilli and staphylococci remain the primary targets of empirical antimicrobial therapy.[1,13] Although *P. aeruginosa* is documented in fewer than 5% of bloodstream infections in the population of hospitalized patients, adequate antipseudomonal antibiotic coverage still must be included in empirical regimens because of the significant morbidity and mortality associated with this pathogen.[1,4,13,19]

At least four different types of empirical parenteral antibiotic regimens are in use: (a) monotherapy with an antipseudomonal cephalosporin (cefepime or ceftazidime) or antipseudomonal carbapenem (imipenem–cilastatin or meropenem); (b) combination therapy with an aminoglycoside plus an antipseudomonal penicillin (piperacillin–tazobactam or ticarcillin–clavulanate), an antipseudomonal cephalosporin, or an antipseudomonal carbapenem; (c) vancomycin plus an antipseudomonal cephalosporin or antipseudomonal carbapenem, with or without an aminoglycoside; and (d) a fluoroquinolone (ciprofloxacin or levofloxacin) in combination with an antipseudomonal cephalosporin, antipseudomonal carbapenem, aminoglycoside, or vancomycin.[1,3–5,13] Each of these regimens has advantages and disadvantages, which are summarized in Table 131–4. There is no overwhelming evidence that any one of these regimens is superior to the others. The overall response to empirical antibiotic regimens in febrile neutropenic cancer patients is approximately 70% to 90% regardless of whether a pathogen is isolated or which antimicrobial regimen is used.[4,13]

Regardless of initial antibiotic selection, all empirical regimens must be monitored appropriately and revised on the basis of documented infections, susceptibilities of bacterial isolates, development of more defined clinical signs and symptoms of infection, or a combination of these factors. Consensus guidelines recommend three general empirical parenteral antibiotic regimens: monotherapy with an antipseudomonal cephalosporin or carbapenem; two-drug therapy without vancomycin (aminoglycoside plus antipseudomonal penicillin, cephalosporin, or carbapenem); or vancomycin plus one to two other drugs (antipseudomonal cephalosporin

TABLE 131-4 Comparative Advantages and Disadvantages of Various Antibiotic Regimens for Empiric Therapy of Febrile Neutropenic Cancer Patients

Regimen	Potential Advantages	Potential Disadvantages
β-Lactam monotherapy (ceftazidime 1–2 g every 8 h, cefepime 1–2 g every 12 h, piperacillin–tazobactam 4.5 g every 6 h, imipenem–cilastatin 0.5 g every 6 h, or meropenem 1 g every 8 h)[a]	Efficacy comparable to combination regimens; decreased drug toxicities; ease of administration; possibly less expensive	Possibly less efficacy in profound neutropenia or prolonged neutropenia; limited gram-positive activity; no potential for additive/synergistic effects; increased selection of resistant organisms; increased colonization and superinfection rates
Antipseudomonal β-lactam plus aminoglycoside (e.g., cefepime 1–2 g every 12 h or ceftazidime 1–2 g every 8 h + gentamicin or tobramycin)[a,b]	Traditional regimen, broad-spectrum coverage; optimal therapy of *Pseudomonas aeruginosa;* rapidly bactericidal; synergistic activity; decreased bacterial resistance; reduction of superinfections	Limited gram-positive activity; potential for nephrotoxicity; need for therapeutic monitoring of aminoglycoside concentrations
Empirical regimens containing vancomycin[c] (ceftazidime 1–2 g every 8 h + vancomycin 0.5–1 g every 6–12 h)[a] ± gentamicin or tobramycin[b]	Early effective therapy of gram-positive infections	No demonstrated benefit of vancomycin empirical therapy vs addition of vancomycin if needed later; increased risk of selection for vancomycin-resistant enterococci; risk of toxicities; excessive cost; need for therapeutic monitoring of vancomycin concentrations
Empirical regimens containing fluoroquinolones (ciprofloxacin 0.4 g every 8–12 h + ceftazidime 1–2 g every 8 h, aminoglycoside, or vancomycin[c] 0.5–1 g every 6–12 h)[a]	Efficacy similar to other regimens when used in combination therapy; no cross-resistance with β-lactams; possibility for oral administration; may be useful in patients with renal impairment in whom aminoglycosides are undesirable	Marginal gram-positive activity; fluoroquinolones not recommended as monotherapy; resistance may develop rapidly
Oral antibiotic regimens (e.g., ciprofloxacin 0.75 g every 12 h or levofloxacin 0.75 g every 24 h + amoxicillin–clavulanate 0.875 g every 12 h or clindamycin 0.6–0.9 g every 8 h)[d]	Efficacy comparable with parenteral therapy in low-risk patients; less expensive; reduced exposure of patients to nosocomial pathogens	Least studied treatment approach; less potent than parenteral antibiotics; requires compliant patient with 24-h access to medical care should clinical instability develop

[a]Dosing guidelines in patients with normal renal function.
[b]Gentamicin or tobramycin 2 mg/kg loading dose, followed by maintenance dose determined by serum concentrations. Choice of specific agent determined according to institutional susceptibilities to individual drugs.
[c]Vancomycin dosing may be guided by serum concentrations.
[d]Clindamycin recommended for patients with β-lactam allergy.

or carbapenem, with or without an aminoglycoside; Fig. 131–1).[1,5] However, other alternative regimens also may be appropriate, based on specific patient characteristics.

Prompt initiation of broad-spectrum empirical antibiotic therapy is essential to prevent early morbidity and mortality in febrile neutropenic patients with cancer. Choice of empirical regimens should take into account the patient's risk of infection and clinical status as well as patterns of hospital infections and susceptibility.

β-Lactam Monotherapy

Several β-lactam antibiotics in current use have been evaluated as monotherapy for management of febrile episodes in neutropenic cancer patients, including antipseudomonal cephalosporins (ceftazidime and cefepime), antipseudomonal penicillins (ticarcillin–clavulanic acid and piperacillin–tazobactam), and antipseudomonal carbapenems (imipenem–cilastatin and meropenem).[1,3,5,13,17] Three different meta-analyses assessing as many as 46 clinical trials involving more than 7,600 patients found no significant differences overall between monotherapy and combination therapy (β-lactam/aminoglycoside) in rates of survival, treatment response, and bacterial/fungal superinfections.[38–40] One study also found a higher rate of adverse effects in aminoglycoside-containing combination regimens.[39] In addition, one analysis found that cefepime monotherapy was associated with a significantly higher risk of mortality compared with the other β-lactams evaluated.[40] Significantly lower response rates for ceftazidime (but not cefepime) monotherapy have been reported in another review of the clinical literature.[41] However, until the results of these conflicting studies can be validated, both ceftazidime and cefepime still are among the monotherapy regimens routinely recommended as appropriate initial therapy of febrile neutropenic patients.[1,5,12,13,40,41]

At least seven clinical studies have documented the efficacy of piperacillin–tazobactam monotherapy for the empirical treatment of febrile neutropenic patients.[17,39–41] Piperacillin–tazobactam has an appropriate overall spectrum of antibacterial activity with good activity against *P. aeruginosa* and other gram-negative organisms as well as many gram-positive pathogens. The 2002 IDSA consensus guidelines did not recommend piperacillin–tazobactam as appropriate for monotherapy due to a relative lack of supportive clinical evidence at the time the guidelines were written.[1] Piperacillin-tazobactam monotherapy is, however, recommended in the 2009 NCCN guidelines and is considered by many clinicians to be appropriate for this use.[5]

Use of monotherapy has several potential advantages and disadvantages (see Table 131–4). Perhaps the most common concerns are those regarding the selection of resistant strains of organisms, such as *P. aeruginosa*, *Enterobacter* spp, and *Serratia* spp, through extended-spectrum β-lactamases and type 1 β-lactamases, especially with ceftazidime.[1,5,7,13] Activity against gram-positive organisms, such as coagulase-negative staphylococci, MRSA, enterococci (including VRE), penicillin-resistant *S. pneumoniae*, and some strains of viridans streptococci is poor with some single β-lactams, but cefepime and antipseudomonal carbapenems have good activity against viridans streptococci and pneumococci.[1] Although ceftazidime has been studied widely and used for treatment of febrile neutropenia, newer agents may be more effective owing to ceftazidime's susceptibility to β-lactamase induction and lower activity against gram-positive organisms.[1,7,41] Doripenem, a newer carbapenem antibiotic, has an appropriate spectrum of activity for empirical treatment of febrile neutropenia but has not been formally studied in this setting. Ertapenem, a carbapenem, and tigecycline, a glycylcycline antibiotic, have excellent activity against many gram-negative organisms but should not be used in

the empirical treatment of febrile neutropenia due to their weaker activity against *P. aeruginosa*.

As with all empirical antibiotic regimens, patients receiving monotherapy should be monitored closely for treatment failure, secondary infections, and development of resistance. Use of monotherapy may not be appropriate in institutions with high rates of gram-positive infections or infections caused by relatively resistant gram-negative pathogens such as *P. aeruginosa* and *Enterobacter* spp. Imipenem–cilastatin and meropenem are less susceptible to inducible β-lactamases and often may be used effectively in these institutions. Overall, similar efficacy has been observed with monotherapy with antipseudomonal β-lactams and aminoglycoside combination therapy for treatment of *P. aeruginosa* infections.[1,13,39–41]

Aminoglycoside Plus Antipseudomonal β-Lactam

Regimens consisting of an aminoglycoside plus an antipseudomonal penicillin, antipseudomonal cephalosporin, or antipseudomonal carbapenem traditionally have been the most commonly used for empirical treatment of febrile neutropenia, although many such regimens may lack adequate gram-positive activity (see Table 131–4).[1] This relative lack of activity remains a concern because of the increasing frequency of gram-positive infections. The choice of aminoglycoside and β-lactam for inclusion in empirical regimens should be based on institutional epidemiology and antimicrobial susceptibility patterns. Use of empirical tobramycin or amikacin may be strongly considered because these agents are generally more active than gentamicin against *P. aeruginosa*. However, gentamicin still is an appropriate choice in many institutions based on known susceptibility patterns in those locations. Similar efficacy is observed with an antipseudomonal penicillin, antipseudomonal cephalosporin, or antipseudomonal carbapenem in combination with an aminoglycoside.[1]

Combinations of broad-spectrum β-lactams and aminoglycosides often provide synergistic activity against bacteria commonly infecting neutropenic patients. The exact role of synergy in the outcome of febrile neutropenic patients treated with empirical antibiotic therapy is somewhat controversial, particularly in light of the efficacy of single-drug regimens. Nevertheless, synergistic combinations of antibiotics appear to be beneficial in patients with persistent profound neutropenia. Moreover, administration of antipseudomonal β-lactams in combination with an aminoglycoside may result in a lower rate of drug resistance.[4]

Aminoglycoside toxicity may be a concern in patients receiving these regimens who are already receiving other nephrotoxic drugs, such as cisplatin and cyclosporine. Administration of aminoglycosides in large single daily doses (once-daily dosing) may be as effective, less costly, and no more toxic than conventional dosing methods.[41] Although once-daily aminoglycoside dosing regimens appear to be safe and effective in these patients, however, data are not sufficient to recommend once-daily dosing for routine use in this population.[1,5,13]

Empirical Regimens Containing Vancomycin

The inclusion of vancomycin in initial empirical therapy of febrile neutropenic cancer patients remains an ongoing debate. This controversy continues because of the increasing incidence of gram-positive infections in this population, particularly MRSA. One approach is to include vancomycin in the initial empirical antibiotic regimen, thereby providing early effective treatment of possible gram-positive infections. Decreased mortality from penicillin-resistant viridans streptococcal infections has been observed when vancomycin was included in initial therapy.[1,13] A second approach is to withhold vancomycin from initial empirical regimens, later adding the drug if gram-positive organisms are isolated from cultures or if there is no response to initial therapy. Support for both these approaches can be found in the medical literature.[1,5,7,13,42,43] Prospective studies and at least two meta-analyses have failed to document increased response rates or decreased mortality with the routine addition of vancomycin to initial empirical regimens, provided that vancomycin can be added later as needed.[1,5,13,42,43] In addition to increased costs of therapy, vancomycin was also associated with increased adverse effects, including nephrotoxicity.[42,43] Finally, concerns remain regarding selection of resistant gram-positive bacteria such as VRE with excessive vancomycin use.[1,5,13]

Inclusion of vancomycin in initial empirical regimens may be more appropriate today because of higher rates of MRSA infections as well as aggressive chemotherapy regimens causing significant mucosal damage that increases the risk for streptococcal infections. Vancomycin is recommended for inclusion in initial empirical regimens in patients at high risk for gram-positive infection, particularly due to MRSA and coagulase-negative staphylococci (including patients with evidence of infection of central venous catheters and other indwelling lines), high risk for viridans streptococcal infection due to severe mucositis, or pneumonitis or soft tissue infection in hospitals with high rates of MRSA infections.[1,3,5,7,13,42,43] Rates of β-lactam resistance among viridans streptococci range from 18% to 29%.[5] Empirical vancomycin use may be justified in institutions using empirical or prophylactic antibiotic regimens without good activity against streptococci (e.g., ciprofloxacin) and in patients known to be colonized with MRSA or β-lactam–resistant pneumococci. In patients with preliminary culture results indicating gram-positive infection, empirical vancomycin is appropriate while the susceptibility results are pending. Lastly, empirical use of vancomycin may be recommended in patients with hypotension or other evidence of cardiovascular impairment or sepsis without an identified pathogen.[1,5,42,43] If empirical vancomycin therapy is initiated and no evidence of gram-positive infection is found after 48 to 72 hours, the drug should be discontinued.[1,4,5] Continuing vancomycin when not warranted results in higher costs, more toxicities, and greater risk of development of VRE.[1,5]

If vancomycin is to be used, vancomycin plus carbapenem regimens may have advantages over vancomycin plus cephalosporin regimens because of lower rates of carbapenem resistance to gram-negative bacilli.[1] Newer antimicrobial agents, such as quinupristin–dalfopristin, linezolid, daptomycin, and telavancin, should be reserved for documented infections caused by multiresistant gram-positive pathogens such as VRE. The role of these drugs in the routine treatment of fever in neutropenic patients is undetermined, and linezolid is associated with myelosuppression.[1,5]

CLINICAL CONTROVERSY

Inclusion of vancomycin into empirical antimicrobial regimens for febrile neutropenia remains controversial. Although the incidence of bacterial infections caused by gram-positive pathogens has increased significantly over the past 2 decades, the benefits of adding vancomycin or other agents with specific gram-positive activity to initial treatment regimens have not been conclusively demonstrated. Although published reviews and meta-analyses recommend against routine initial use of vancomycin, the practice remains widespread in actual clinical practice.

Fluoroquinolones as a Component of Empirical Regimens

Because the fluoroquinolone antibiotics have broad-spectrum activity (particularly against gram-negative pathogens), rapid bactericidal activity, and favorable pharmacokinetic and toxicity profiles, these agents have been investigated as empirical therapy for febrile neutropenic patients. Ciprofloxacin is the preferred quinolone for use in this clinical setting because of its relatively better activity against *P. aeruginosa* and more extensive evidence-based support for its use.[1,13] Response rates to quinolone-containing combination regimens are comparable to those obtained with the other regimens described previously.[1,4,5] Ciprofloxacin is not recommended for monotherapy, however, because of its relatively poor activity against gram-positive pathogens, particularly streptococci, and variable response rates in clinical studies.[1] Quinolones should also not be used as empirical therapy in patients who have received quinolones as infection prophylaxis because of the risk of drug resistance.[1,5,13] Rates of fluoroquinolone resistance are increasing, and streptococcal treatment failures are a concern.[19,44] Although fluoroquinolones are not generally considered first-line empirical therapy, they may be useful as one component of combination regimens in patients with allergies or other contraindications to first-line agents.[1,5]

Oral Antibiotic Therapy for Management of Febrile Neutropenia

An individual patient's risk of severe infection determines appropriate antibiotic therapy and the setting for administration (see Table 131–3).[1,4,5] Risk stratification is based on several parameters, including duration and degree of neutropenia, type of cancer and its management (including history of HSCT), clinical status, comorbidities, and response to empirical antimicrobial therapy.[1] Because of the excellent spectrum of activity and favorable pharmacokinetics of relatively newer oral antibiotics, particularly the fluoroquinolones, oral antibiotics have an important role in the management of selected patients. In patients at low risk for severe or complicated bacterial infection, empirical therapy with broad-spectrum oral antibiotic agents achieves similar patient outcomes as parenteral antibiotics, with response rates of 77% to 95%.[1,4,13,34–37] The availability of oral antibiotics with broad-spectrum activity has made possible the treatment of febrile neutropenia in low-risk patients completely in the outpatient setting. Patients with solid tumors undergoing conventional chemotherapy with an expected duration of neutropenia of less than 7 to 10 days and who are clinically stable may be appropriate candidates for oral antibiotic therapy administered on an outpatient basis.[1,4,5,13,34–37] Fluoroquinolones, either as monotherapy or in combination with amoxicillin–clavulanate (or clindamycin for penicillin-allergic patients) for enhanced gram-positive coverage, have been most commonly studied for outpatient therapy in low-risk patients. IDSA and NCCN guidelines recommend oral antibiotic therapy with ciprofloxacin plus amoxicillin–clavulanate in clinically stable low-risk adults (particularly those with recovering neutrophils) with no focus of bacterial infection and no signs of infection other than fever.[1,5] Oral cephalosporins such as cefixime also may be suitable for outpatient treatment.[1] Careful patient selection obviously is required for such management strategies. Important patient characteristics include a history of medication compliance, good caregiver support, and close proximity to medical care in the event of failure to respond to outpatient antibiotic therapy. Benefits of oral therapy on an outpatient basis include increased convenience and quality of life for patients and caregivers and reduced exposure to multidrug-resistant institutional pathogens.[1,5] Outpatient therapy of low-risk patients now is common practice in most institutions.

In patients at moderate risk for severe bacterial infection, oral antibiotics may play a role in step-down therapy. Carefully selected neutropenic patients may be safely switched from broad-spectrum parenteral therapy to oral antibiotic regimens (e.g., ciprofloxacin plus amoxicillin–clavulanate) with response rates comparable to patients remaining on IV therapy.[13,34–37] Patient selection criteria generally include defervescence within 72 hours of initiation of parenteral therapy, hemodynamic stability, absence of positive cultures or a discernible site of infection, and ability to take oral medications. Many of these patients are able to complete their course of therapy at home.[1,13,35–37] Changing parenteral antimicrobials to oral regimens in carefully selected patients is now relatively common practice and allows for less expensive hospitalizations and earlier patient discharges.

ANTIMICROBIAL THERAPY AFTER INITIATION OF EMPIRICAL THERAPY

6 After initiation of empirical antimicrobial therapy, judicious assessment of febrile neutropenic cancer patients is mandatory to evaluate response, clinical status, laboratory data, and potential need for therapy adjustments. After 72 hours or more of empirical antimicrobial therapy, the clinical status and culture results of febrile neutropenic patients should be reevaluated to determine whether therapeutic modifications are necessary. Additions or modifications to the initial antimicrobial regimen likely will be required for patients with ANC less than 500 cells/mm^3 for more than 1 week. Modifications of antimicrobial therapy should be based on clinical and laboratory data; antibiotic therapy should be optimized based on culture results. However, during periods of neutropenia, patients generally should continue to receive broad-spectrum therapy because of risk of secondary infections or breakthrough bacteremias when antimicrobial coverage is too narrow.[1,5,13]

In patients who become afebrile after 3 to 5 days of therapy with no infection identified, it is generally optimal to continue antibiotic therapy until neutropenia has resolved (ANC ≥500 cells/mm^3). Some clinicians switch therapy to an oral regimen (e.g., ciprofloxacin plus amoxicillin-clavulanate) after 2 days of IV therapy in low- to moderate-risk patients who become afebrile and have no evidence of infection. This approach may facilitate earlier hospital discharge. In high-risk patients, the parenteral antibiotic regimen should be continued for at least 7 days.[1,5] However, in afebrile patients with prolonged neutropenia but no signs or symptoms of infection, consideration can be given to discontinuing antibiotic therapy, provided patients can be observed carefully and have ready access to medical care.

The optimal management of patients who remain febrile in the absence of microbiologic or clinical documentation of infection remains highly controversial. Persistently febrile patients should be evaluated carefully, but modifications generally are not made to initial antimicrobial regimens within the first 3 to 5 days of therapy unless there is evidence of clinical deterioration (see Fig. 131–1).[1,4,5] It is important to note that the persistence of fever does not necessarily mean failure of a given antimicrobial regimen; up to 25% of neutropenic patients have fever due to noninfectious causes.[8] This is particularly true if patients are otherwise clinically stable. Fever after 3 or more days of antibiotic therapy can be due to a number of causes, including nonbacterial infection, resistant bacterial infection or infection slow to respond to therapy, emergence of a secondary infection, inadequate drug concentrations, drug fever, fever at an avascular site (e.g., catheter infection or abscess), or noninfectious causes such as tumor or administration of blood products.[1,4,5,13] Patients with documented infection who are receiving appropriate antimicrobial therapy (based on in vitro susceptibility tests) often remain febrile until resolution of neutropenia occurs.

Therefore, the same antibiotic regimen can be continued in patients who remain febrile despite 3 to 5 days of antibiotic therapy but are otherwise clinically stable, especially if neutropenia is expected to resolve within 1 week. However, antibiotic regimens may require modification in patients experiencing toxicities as well as in patients with evidence of progressive disease or documentation of an organism not covered by the initial regimen. When a causative organism is identified, specific therapy directed at the organism should be included; however, patients should continue to receive broad-spectrum therapy while they remain neutropenic.[1,3,4,5,13] Need for addition of vancomycin should be considered as warranted by clinical and laboratory findings; however, if vancomycin was included in the initial empirical regimen and the patient is still febrile after 3 days of therapy, discontinuation of vancomycin should be considered to reduce the risk of toxicities or resistance.

Initiation of Antifungal Therapy

Neutropenic patients who remain febrile despite 5 or more days of broad-spectrum antibiotic therapy are candidates for antifungal therapy. A high percentage of febrile patients who die during prolonged neutropenia have evidence of invasive fungal infection on autopsy, even though many had no evidence of fungal disease before death.[26] Persistence of fever or development of a new fever during broad-spectrum antibiotic therapy may indicate the presence of a fungal infection, most commonly due to *Candida* or *Aspergillus* spp.[13,26] Blood cultures are positive in fewer than 50% of neutropenic patients with invasive fungal infections.[13,31] Rapid, sensitive diagnostic tests for fungi such as serum β–D-glucan assay are not yet in common usage and waiting for isolation of fungal organisms is associated with high morbidity and mortality; the empirical addition of antifungal therapy is thus justified in this clinical setting.[1,13,31] Therefore, empirical antifungal therapy should be initiated after 5 to 7 days of broad-spectrum antibiotic therapy at adequate doses to treat undiagnosed fungal infection and prevent fungal superinfection in high-risk febrile neutropenic patients.[27]

Evidence-based recommendations from published guidelines for management of suspected or documented fungal infections in neutropenic patients are summarized in Table 131–2.[27,33] Empirical coverage for both *Candida* spp and *Aspergillus* should be considered because these organisms are responsible for more than 90% of fungal infections in neutropenic cancer patients.[6,26] *Aspergillus* is particularly common in patients with hematologic malignancies and in patients with hematologic malignancies undergoing HSCT; therefore, amphotericin B traditionally has been preferred for these patients.[13,45,46] In the setting of febrile neutropenia, lipid-associated amphotericin B (LAMB) products are similar in efficacy to conventional amphotericin B while causing fewer toxicities. LAMB products are thus almost exclusively recommended over conventional amphotericin B despite the significantly higher cost without clear improvement in efficacy.[27,33,45–47] Although the use of higher doses of LAMB has been advocated in an effort to improve efficacy, one study demonstrated that lower doses (3 mg/kg) of liposomal amphotericin B were as efficacious as higher doses (10 mg/kg) with lower cost and fewer toxicities.[48]

The azole compounds fluconazole, itraconazole, and voriconazole are also used in the management of febrile neutropenia.[27,33,49] Despite the increased cost and toxicities of LAMB, concerns regarding the emergence of *Candida* strains with decreased azole susceptibility and unclear efficacy advantages relative to other agents have prevented these agents from replacing amphotericin B as the gold standard in persistently febrile neutropenic patients.[32,33,45,46] Fluconazole has good efficacy against *C. albicans* but lacks activity against molds such as *Aspergillus*. The use of fluconazole as an alternative to amphotericin B for empirical antifungal therapy is thus perhaps most appropriate in hospitals in which infections due to *Aspergillus* or non-*albicans* strains of *Candida* are not common.[1,45,46] If fluconazole is used as antifungal prophylaxis in cancer patients, it should not be included in empirical antifungal regimens. Voriconazole has shown efficacy in the treatment of documented invasive fungal infections but may be less desirable for empirical therapy in febrile neutropenic patients due to lack of improved efficacy compared to amphotericin B.[31,45,46] Voriconazole is recommended as appropriate for empirical antifungal therapy in neutropenic patients,[33] but is often limited to allogeneic HSCT patients and patients with relapsed leukemia who are at very high risk of invasive *Aspergillus* infections.[31,49–51] Itraconazole has similar efficacy as amphotericin B, with fewer toxicities. However, current lack of a parenteral dosage form, sometimes erratic oral absorption which often necessitates the use of serum concentration monitoring, numerous potential drug-drug interactions, and availability of many other antifungal options has limited the use of itraconazole as a preferred treatment option.[49–51]

The echinocandin antifungals (caspofungin, micafungin, and anidulafungin) are attractive agents for treatment of febrile neutropenia because of their broad spectrum of antifungal activity and favorable adverse effect profiles. Caspofungin is as effective as, and also generally better tolerated than, liposomal amphotericin B for empirical treatment of neutropenic patients with persistent fever.[49–51] Therefore, caspofungin is considered an appropriate alternative to LAMB and voriconazole.[5,27,31,33,45,46,50] Micafungin and anidulafungin have not been as well studied specifically in neutropenic patients and are not routinely recommended for routine empirical use at this time.[5,27,33]

As with antibiotic therapy, the optimal duration of antifungal therapy remains controversial. Most clinicians agree that antifungal therapy can be discontinued when neutropenia has resolved in clinically stable patients with no evidence of fungal infection. In neutropenic patients, antifungal therapy generally should be continued for at least 2 weeks in the absence of signs and symptoms of active fungal disease, but many experts advocate continuing therapy until resolution of the neutropenia.[4,13,27,45,46] In neutropenic patients with documented fungal disease, antifungal therapy should be directed at the causative organism, and therapy should be continued for at least 2 weeks after clinical and culture data indicate resolution of the infection.[27] In addition to fungal infections, other causes of persistent fever of unknown origin include resistant bacterial infection, tissue necrosis as a result of underlying tumor, nonbacterial and nonfungal infection (e.g., viral, mycobacterial, or parasitic), and drug or blood product administration. The persistence of fever should not be considered the sole indication for modification of antifungal regimens, assuming that an agent active against *Aspergillus* was initially selected.[31,45,46] Treatment recommendations for specific fungal infections are given in Table 131–5.

Initiation of Antiviral Therapy

Febrile neutropenic patients with vesicular or ulcerative skin or mucosal lesions should be evaluated carefully for infection due to HSV or varicella-zoster virus (VZV). Mucosal lesions from viral infections provide a portal of entry for bacteria and fungi during periods of immunosuppression. If viral infection is presumed or documented, neutropenic patients should receive aggressive antiviral therapy to aid healing of primary lesions and prevent disseminated disease. Acyclovir traditionally has been used in this population. However, the newer antivirals valacyclovir and famciclovir have better oral absorption and more convenient dosing schedules. Routine use of antiviral agents in the management of patients without mucosal lesions or other evidence of viral infection

TABLE 131-5 Infectious Complications after Bone Marrow and Solid-Organ Transplantation: Syndromes of Disease and Treatment Guidelines

Pathogen	Syndromes of Disease	Treatment
Bacterial		
Gram-negative aerobic bacilli (Enterobacteriaceae, *Pseudomonas aeruginosa*, *Haemophilus influenzae*)	Blood, urinary tract, pulmonary, abdomen	*Empiric:* Ceftazidime 1–2 g every 8 h + aminoglycoside,[a,b] cefepime 1–2 g every 12 h + aminoglycoside[a,b]; piperacillin–tazobactam 3.375–4.5 g every 4–6 h; imipenem–cilastatin 0.25–0.5 g every 6 h ± aminoglycoside[a,b] *Definitive:* According to culture and sensitivity results
Gram-positive cocci (*Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus pneumoniae*, *Enterococcus faecalis*)	Skin, blood, urinary tract, pulmonary, abdomen	*Empiric:* Nafcillin 1–2 g every 4–6 h; vancomycin 0.5–1 g every 6–12 h[c] *Definitive:* According to culture and sensitivity results
Legionella spp	Pulmonary	Erythromycin 0.5–1 g every 6 h; ciprofloxacin 0.4 g every 8–12 h; levofloxacin 0.75 g every 24 h
Listeria monocytogenes	Central nervous system	Ampicillin 1–2 g every 4–6 h with gentamicin[a]; trimethoprim–sulfamethoxazole 4 mg/kg every 12 h[d]
Nocardia spp	Skin, pulmonary, central nervous system	Sulfadiazine 1 g every 4–6 h; trimethoprim–sulfamethoxazole 4 mg/kg every 12 h[d]
Fungal		
Candida spp[e]	Blood, urinary tract, mucous membranes, skin	Clotrimazole 10 mg 5 times daily; nystatin 100,000 units every 6 h; fluconazole 100–800 mg daily; itraconazole 200–400 mg daily; amphotericin B 0.3–0.7 mg/kg/day ± 5-flucytosine 100–150 mg/kg/day divided every 6 h; lipid-associated amphotericin B 3–5 mg/kg daily; caspofungin 50 mg daily; micafungin 100 mg daily; anidulafungin 100 mg daily
Aspergillus spp[f]	Skin, pulmonary, central nervous system	Voriconazole 4 mg/kg every 12 h; lipid-associated amphotericin B 3–5 mg/kg daily; caspofungin 50 mg daily; micafungin 100–150 mg daily; posaconazole 400 mg every 12 h; itraconazole 400 mg daily
Cryptococcus neoformans	Skin, pulmonary, central nervous system	Lipid-associated amphotericin B 3-5 mg/kg/day + 5-flucytosine 100 mg/kg/day; fluconazole 400 mg daily
Zygomycetes (*Mucor*)	Rhinocerebral disease	Lipid-associated amphotericin B 4–5 mg/kg daily; posaconazole 200 mg every 8 h[e]
Viral		
Herpes simplex virus	Skin, central nervous system, mucous membranes, pulmonary	Acyclovir 5–10 mg/kg every 8 h; foscarnet 60 mg/kg every 8 h
Cytomegalovirus	Pulmonary, blood, urinary tract, gastrointestinal tract	Ganciclovir 5 mg/kg every 12 h; foscarnet 60 mg/kg every 8 h; hyperimmune globulins 100–500 mg/kg every 1–2 wk
Varicella-zoster virus	Skin, disseminated disease	Acyclovir 10 mg/kg every 8 h; foscarnet 60 mg/kg every 8 h
Epstein-Barr virus	Lymphoproliferative disease	No effective treatment
Papovaviruses (BK, JC)	Skin, central nervous system	No effective treatment
Protozoal/parasitic		
Pneumocystis jiroveci	Pulmonary	Trimethoprim–sulfamethoxazole 15–20 mg/kg/day divided every 6 h[d]; atovaquone 750 mg every 12 h; pentamidine 4 mg/kg daily; dapsone 100 mg daily + trimethoprim 15–20 mg/ kg/day divided every 6 h; clindamycin 450–600 mg every 6 h + primaquine 15 mg daily
Toxoplasma gondii	Central nervous system	Pyrimethamine 50–100 mg daily + sulfadiazine 1 g every 4–6 h[g]; pyrimethamine 50–100 mg daily + clindamycin 450–600 mg every 6 h[g]
Strongyloides stercoralis	Pulmonary, central nervous system	Thiabendazole 25 mg/kg every 12 h (maximum 3 g/day)

[a]Gentamicin or tobramycin 2 mg/kg loading dose, followed by maintenance dose determined by serum concentrations. Choice of specific agent determined according to institutional susceptibilities to individual drugs.
[b]For penicillin-allergic adults, use ciprofloxacin 0.4 g every 8–12 h plus an aminoglycoside.
[c]Vancomycin dosing may be guided by serum concentrations.
[d]Based on the trimethoprim component of the combination.
[e]Refer to the Clinical Practice Guidelines of the Infectious Diseases Society of America (*reference 27*) for selection and dosing of antifungal agents for specific infections.
[f]Refer to the Clinical Practice Guidelines by the Infectious Diseases Society of America (*reference 33*) for selection and dosing of antifungal agents for specific infections.
[g]Folinic acid (5–10 mg/day) often recommended in conjunction with pyrimethamine-containing regimens for prevention of bone marrow toxicity.

generally is not recommended.[1,5] Treatment recommendations for viral infections are given in Table 131–5.

Duration of Antimicrobial Therapy

7 The optimal duration of antimicrobial therapy in the neutropenic cancer patient remains controversial. Decisions regarding discontinuation of empirical antimicrobial therapy often are more difficult and complex than those regarding initiation of therapy (see Fig. 131–1). One point on which experts agree, however, is that the most important determinant of the total duration of antibiotic therapy is the patient's ANC.[1,3,5,13] If ANC is ≥500 cells/mm^3 for 2 consecutive days, if the patient is afebrile and clinically stable for 48 to 72 hours or more, and if no pathogen has been isolated, then antibiotics can be discontinued. Some clinicians advocate that patients with ANC less than 500 cells/mm^3 be maintained on antibiotic therapy until resolution of neutropenia, even if they are afebrile. However, prolonged antibiotic use has been associated with superinfections resulting from resistant bacteria and fungi and increases the risk of antibiotic-related toxicities.[1,5,13] If low-risk patients are stable clinically but the ANC still is less than 500 cells/mm^3, antibiotics may be discontinued after a total of 5 to 7 afebrile days. However, patients with profound neutropenia (ANC <100 cells/mm^3), mucosal lesions, or unstable vital signs or other risk factors should continue to receive antibiotics until ANC has increased to 500 cells/mm^3 or greater or the patient is stable clinically.[1,5,13]

Patients who are persistently neutropenic and febrile, but who are stable clinically with no active site of infection, often can be successfully discontinued from antimicrobials after at least 2 weeks of therapy. However, these patients must be monitored carefully because reinstitution of antibiotics may be necessary.[1,5,13] An alternative approach is to place these patients on antimicrobial prophylaxis (discussed below in Prophylaxis of Infections in Neutropenic Cancer Patients). Patients with documented infections should receive antimicrobial therapy until the infecting organism is eradicated and signs and symptoms of infection have resolved (at least 10–14 days of therapy).

Consensus guidelines provide useful information regarding the management of febrile episodes in cancer patients with neutropenia.[1,5] However, therapy (including initial empirical regimens, modifications, and duration of treatment) must be individualized based on individual patient parameters and response to therapy.

CLINICAL CONTROVERSY

The optimal time to stop empirical antimicrobial therapy in patients who remain persistently febrile remains a key controversy in the overall management of febrile neutropenia in cancer patients. One unresolved issue is whether the patient's neutropenia must be resolved prior to discontinuing antimicrobial therapy. The patient's individual risk of severe infection (determined by extent and duration of neutropenia as well as other risk factors) helps to guide treatment decisions in this setting.

Colony-Stimulating Factors

Because resolution of neutropenia is arguably the most important determinant of patient outcome from both febrile episodes and documented infections, numerous studies have evaluated hematopoietic colony-stimulating factors (CSFs) (sargramostim [granulocyte-macrophage colony-stimulating factor] and filgrastim [granulocyte colony-stimulating factor]) as adjunct therapy to antimicrobial treatment of febrile neutropenic cancer patients.[52] These studies consistently found that use of CSFs reduces the total duration and severity of chemotherapy-related neutropenia; some studies have also shown fewer hospitalizations and decreased hospital length of stay.[52,53] However, these studies have failed to demonstrate consistent benefits of CSFs compared with placebo in relation to important outcomes such as decreased overall mortality or infection-related mortality.[52,53] Evidence-based guidelines from the American Society of Clinical Oncology (ASCO) and the NCCN recommend that CSFs should not be routinely used in patients with uncomplicated fever and neutropenia.[52,54] However, CSFs should be considered in patients who are at high risk for infection–associated complications, or who have factors that are predictive of poor clinical outcomes.[52,54] These factors are summarized in Table 131–6. Patients with prolonged neutropenia and documented severe infections who are not responding to appropriate antimicrobial therapy may also benefit from treatment with CSFs.[52,54] Clinical judgment must be exercised in determining which patients may benefit from judicious use of these expensive agents.

Direct transfusion of neutrophils has also been studied for treatment of febrile neutropenia or documented infections.[55,56] Routine use of neutrophil transfusions is not generally supported by data demonstrating improved clinical outcomes. However, use may be considered in patients with profound prolonged neutropenia with severe documented infections and in whom causative organisms have not been eradicated with appropriate antimicrobial therapy in combination with CSFs.[1,5,55] At present, the use of neutrophil transfusions is considered investigational and is not recommended for routine management of febrile neutropenic patients.[55]

TABLE 131-6 Recommendations for Use of Colony-Stimulating Factors in the Management of Neutropenic Cancer Patients and Those Undergoing Hematopoietic Stem Cell Transplantation

A. Primary prophylaxis of febrile neutropenia

1. Colony-stimulating factors (CSFs) (filgrastim, pegfilgrastim, or sargramostim) may be considered in patients who have a high risk of FN (>20% incidence) based on myelotoxicity of the planned chemotherapy regimen.
2. When risk of febrile neutropenia is 10%–20%, CSFs may be considered in the presence of certain patient and clinical factors predisposing to increased complications from prolonged neutropenia, including: patient age >65 years; poor performance status; extensive prior treatment including large radiation ports; administration of combined chemoradiotherapy; cytopenias due to bone marrow involvement by tumor; poor nutritional status; presence of open wounds or active infections; previous surgery; poor renal function; liver dysfunction, particularly when evidenced by increased bilirubin; and lack of antibiotic prophylaxis.

B. Secondary prophylaxis of febrile neutropenia

1. CSFs (filgrastim, pegfilgrastim, or sargramostim) recommended for patients who experienced neutropenic complications from prior cycles of chemotherapy, and in which a reduced dose may compromise disease-free or overall survival or treatment outcome.

C. Therapeutic use in febrile neutropenia

1. CSFs should not be routinely used for patients with neutropenia who are afebrile.
2. CSFs (filgrastim or sargramostim only) may be considered in patients with febrile neutropenia who are at high risk for infection-associated complications, or who have prognostic factors that are predictive of poor clinical outcomes, including: profound neutropenia (absolute neutrophil count <100 cells/mm^3); expected prolonged period of neutropenia (>10 days); patient age >65 years; uncontrolled primary disease; sepsis syndrome, or severe infection manifest by hypotension and multiorgan dysfunction; pneumonia; invasive fungal infection; other clinically documented infection; hospitalized at the time of the development of fever; or severe complications during previous episode of febrile neutropenia.

D. Reduction in duration of neutropenia in HSCT

1. CSFs are recommended to mobilize peripheral-blood progenitor cells (PBPC) prior to chemotherapy and to reduce the duration of neutropenia after autologous PBPC transplantation.

Data from references 52–54 and 59.

PROPHYLAXIS OF INFECTIONS IN NEUTROPENIC CANCER PATIENTS

8 Owing to the potential morbidity and mortality of infections in neutropenic cancer patients, environmental modifications and prophylactic antimicrobial regimens have been implemented to prevent these complications. The overall goal of antimicrobial prophylaxis in cancer patients is to decrease the number and severity of systemic infections during prolonged periods of neutropenia.

General Measures

Because approximately 50% of pathogens infecting neutropenic cancer patients are acquired in the hospital, reducing acquisition of infectious organisms from the environment is a basic component in controlling nosocomial infections.[1,2,5,6,13] Neutropenic patients should be placed in reverse isolation (isolation to protect patients from contracting infections after exposure to others), with strict adherence to infection control guidelines by hospital personnel.[1,5,13] Proper meticulous handwashing by hospital personnel is a simple yet very effective infection control measure. To reduce the risk of

infection caused by airborne pathogens, such as *Aspergillus* spp, laminar airflow rooms are used at some cancer centers performing HSCT. Laminar airflow rooms work by directing filtered air away from the patient, thus minimizing the risk of infection from airborne or environmental pathogens. Laminar airflow rooms are expensive, and use of these protective environments does not improve overall survival in HSCT recipients.[6,13]

Bacterial Infections

Combinations of oral nonabsorbable antibiotics, such as gentamicin, nystatin, vancomycin, polymyxin B, and colistin, have been widely studied as a means of reducing colonization of the GI tract with virulent pathogens, such as *P. aeruginosa*, and their translocation into the bloodstream. Although clinical trials have demonstrated that selective intestinal decontamination with oral nonabsorbable antibiotics successfully reduces infections, these regimens are not routinely recommended for prophylaxis because of problems that include unpalatability, high cost, and frequent adverse effects (e.g., nausea, vomiting, diarrhea).[1,2,4–6,13] Use of nonabsorbable antibiotic regimens has been associated with the development of resistance to aminoglycosides among gram-negative bacilli, rendering the aminoglycosides useless as treatment alternatives for ensuing infections.[1,2,13] Owing to concerns regarding development of resistance, prophylaxis with aminoglycosides and vancomycin should be avoided.[1,5]

Selective decontamination with systemic antimicrobial prophylaxis has been combined with oral agents, particularly the fluoroquinolones.[1,2,57] Prospective clinical trials have shown that orally absorbed prophylactic antibiotics, including trimethoprim–sulfamethoxazole and fluoroquinolones, are more effective and better tolerated than nonabsorbable antibiotics.[1,5] Most placebo-controlled studies indicate that trimethoprim–sulfamethoxazole significantly reduces infection rates in cancer patients.[1,5] Although trimethoprim–sulfamethoxazole is effective as prophylaxis against *P. jiroveci*, its lack of activity against *P. aeruginosa* is worrisome, particularly in institutions where pseudomonal infections are frequent.[1] Other concerns with trimethoprim–sulfamethoxazole prophylaxis include selection of resistant organisms, predisposition to development of oral fungal infections, and delay in bone marrow recovery resulting in prolonged neutropenic episodes.[1,5,6]

Numerous studies have shown that oral fluoroquinolones are more effective than placebo, nonabsorbable antibiotics, or trimethoprim–sulfamethoxazole in preventing gram-negative infections in neutropenic cancer patients.[57,58] Fluoroquinolone prophylaxis during periods of neutropenia decreases the incidence of fever and microbiologically documented gram-negative infections and may decrease the risk of death in these patients.[57,58] However, there are several potential limitations to their use. In particular, ciprofloxacin may lack adequate gram-positive activity. As a result, combination of ciprofloxacin with a second agent providing enhanced gram-positive activity (e.g., rifampin, penicillin, or a macrolide) may be required for effective prophylaxis.[1,5] Although fluoroquinolone prophylaxis has been associated with the development of resistant gram-negative organisms, two meta-analysis reports suggest that the risk of infection with resistant pathogens is not significantly increased.[57,58] Also the risk of colonization or infection with strains resistant to the prophylactic agent is lower with fluoroquinolones than with trimethoprim–sulfamethoxazole. However, patients experiencing breakthrough infection during fluoroquinolone prophylaxis should not be subsequently placed on a fluoroquinolone-containing empirical antibiotic regimen.[1,5]

Although studies have concluded that the benefits of prophylaxis with fluoroquinolones outweigh the potential risks, antibacterial prophylaxis in general remains somewhat controversial due to continued concerns regarding the potential for development of resistant bacteria, high cost, and lack of impact on patient survival.[1,2,5] Therefore, antibacterial prophylaxis is not recommended routinely for all neutropenic patients. Prophylaxis (with trimethoprim–sulfamethoxazole or quinolone plus penicillin) generally is indicated for patients expected to be profoundly neutropenic for more than 1 week, such as HSCT patients.[1,6] Additional risk factors that may provide justification for prophylaxis include mucous membrane or skin lesions, presence of indwelling catheters, need for instrumentation or severe periodontal disease.[1,5] Neutrophil recovery eliminates the need for continued prophylaxis, and recovery may be facilitated by use of CSFs.[52] CSFs have also been formally recommended by the ASCO and the European Organisation for Research and Treatment of Cancer (EORTC) for primary prevention of febrile neutropenia in high-risk patients (see Table 131–6).[52,59]

Fungal Infections

Because neutropenic patients are at risk for mucocutaneous and invasive fungal infections that are difficult to diagnose and treat in this population, antifungal prophylaxis can be considered during high-risk periods at institutions where fungal infections in cancer patients occur frequently.[60] The goal of antifungal prophylaxis is to prevent development of invasive fungal infections during periods of risk, thereby reducing morbidity and mortality. A meta-analysis of antifungal prophylaxis in 38 trials involving more than 7,000 cancer patients reported a decrease in the use of parenteral antifungal therapy, superficial and invasive systemic fungal infections, and fungal infection–related mortality rate.[61] Antifungal prophylaxis in these studies resulted in decreased mortality in patients with prolonged neutropenia and HSCT but no effect on rates of invasive *Aspergillus* infections.

Although the choice of antifungal prophylaxis agents remains controversial, fluconazole prophylaxis (400 mg/day) has been particularly well studied and reduces the incidence of both superficial and systemic fungal infections; it also significantly decreases mortality from fungal infections in patients with leukemia and HSCT recipients.[60,61] However, use of fluconazole prophylaxis has contributed to the emergence of infections caused by *C. krusei* and *C. glabrata*, pathogens that frequently are resistant to fluconazole and other azole-type antifungal agents.[32,60] Therefore, routine antifungal prophylaxis with oral fluconazole (400 mg/day), itraconazole oral solution (200 mg/day), posaconazole (200 mg 3 times daily), or caspofungin (50 mg/day) are now routinely recommended starting with induction chemotherapy.[27] The choice of a specific agent should be determined by the types of fungal isolates at individual institutions.[27,62] After initiation, antifungal prophylaxis should be continued until resolution of neutropenia or the need for institution of antifungal therapy for suspected/documented infection.[27]

Itraconazole, low to moderate doses of amphotericin B, intranasal and aerosolized amphotericin B, lipid-associated amphotericin B products, voriconazole, and the echinocandin agents have been investigated for *Aspergillus* prophylaxis in neutropenic patients.[6,33,63] Posaconazole (200 mg suspension 3 times daily) was more effective than either fluconazole 400 mg/day or itraconazole 200 mg twice daily in the prevention of *Aspergillus* and other invasive fungal infections in patients with hematologic malignancies and prolonged neutropenia.[33,63] However, outside of the HSCT setting, posaconazole is currently only recommended for routine prevention of *Aspergillus* infections in neutropenic patients with hematologic malignancies.[33]

Other Infections

Use of trimethoprim–sulfamethoxazole in cancer patients at risk for *P. jiroveci* pneumonia has substantially reduced the incidence

of this protozoal infection.[1] Antiviral prophylaxis with acyclovir, valacyclovir, or famciclovir is used in most centers to reduce the risk of HSV reactivation in patients with acute leukemia undergoing intensive chemotherapy. Varicella vaccine provides good protection (90%) in leukemic children and may be useful in seronegative adults, although the vaccine has been less well studied in this population.

When considering use of antimicrobial (antibacterial, antifungal, antiprotozoal, and antiviral) prophylaxis in neutropenic patients with cancer, the risks and benefits of prophylaxis must be weighed against issues with development of resistance, toxicities, and other concerns.

PHARMACOECONOMIC CONSIDERATIONS

⑩ As in all areas of modern healthcare, attention has been directed increasingly toward providing cost-effective management of febrile neutropenia in cancer patients. Use of oral and/or outpatient antimicrobial therapy in low-risk patients is an effective, less costly alternative that is preferred by patients.[1,5,65] Potent oral antimicrobials facilitate conversion from IV antibiotics to oral therapy when appropriate. Judicious use of antimicrobials also helps to contain costs. In the situation of febrile neutropenia in a cancer patient, clinicians often are tempted to treat suspected/documented infections extremely aggressively; however, following guidelines such as those published by the IDSA and NCCN helps to assure the most appropriate use of available antimicrobials. Future consequences of antimicrobial overuse, such as resistance and limited treatment options, must be considered when choosing antimicrobial therapy for any indication, including management of febrile neutropenia. Each institution should examine its own infection and susceptibility patterns and use this information to guide empirical treatment decisions while individualizing therapy for each patient.

EVALUATION OF THERAPEUTIC OUTCOMES

⑩ Close monitoring of febrile neutropenic patients, including both clinical and laboratory parameters, is essential for early detection and treatment of infectious complications. Three general therapeutic outcomes have been defined in the setting of febrile neutropenia: (a) success (survival during the febrile episode until resolution of neutropenia by judicious selection of empirical antimicrobial therapy), (b) success with modification (same as (a) but with additions/ modifications to empirical therapy), and (c) failure (death during febrile neutropenia).[13] Because many of the drugs that can be used in this setting (e.g., aminoglycosides and amphotericin B) have significant toxicity potential, careful attention must be paid to prevention and management of drug-related adverse effects. Evaluations of the parameters given in the Clinical Presentation are appropriate to help monitor and guide therapy. In addition, the NCCN guidelines for febrile neutropenia provide comprehensive recommendations on clinical/laboratory monitoring parameters, including schedules.[5] The reader is referred to individual chapters within this book for more detailed discussions of monitoring parameters related to specific types of infections (e.g., pneumonia and urinary tract infections).

INFECTIONS IN PATIENTS UNDERGOING HSCT

① Infection remains a major barrier to successful HSCT.[66,67] Recipients of HSCT are at enhanced risk for infection because of prolonged periods of neutropenia. In addition, patients receiving allogeneic or matched unrelated donor transplants have immune system insults imposed by prolonged immunosuppressive drug therapy for prevention and treatment of graft-versus-host disease (GVHD). Intensive pre-transplant conditioning regimens (high-dose chemotherapy and total-body irradiation), as well as GVHD itself, often disrupt protective barriers, such as mucous membranes, skin, and the GI tract, placing patients at further risk of infection. Patients experiencing failure to engraft have extended periods of profound neutropenia often resulting in death from infectious causes. The U.S. Food and Drug Administration (FDA) approved sargramostim for marrow graft failure in both autologous and allogeneic transplants.

ETIOLOGY AND CLINICAL PRESENTATION OF INFECTIONS

② ⑩ The timing with which specific types of infections typically occur following HSCT is shown in Figure 131–2, but the relative incidence and importance of specific pathogens vary greatly according to the specific type of HSCT performed. Patients receiving allogeneic transplants are at greatest risk for infection after HSCT and are predisposed to earlier and more severe infections with opportunistic pathogens such as *Aspergillus*. The presence of GVHD also has an impact on the incidence and timing of various infections, including invasive fungal infections.

After administration of intensive conditioning regimens to eliminate malignant cells and prevent rejection of donor cells, patients may remain profoundly neutropenic for 3 to 4 weeks. During this pre-engraftment period, patients are at risk for the same types of infectious complications that occur in other granulocytopenic cancer patients (e.g., bacterial and fungal infections) and should be managed accordingly (see Table 131–1). Table 131–5 lists regimens for treatment of specific infections.

Patients undergoing HSCT are at significant risk for serious bacterial infections.[66–68] The risk of bacterial infection is particularly increased in patients undergoing allogeneic transplantation and those with GVHD. Gram-negative bacteremia occur in approximately 20% of patients, and mortality rates may reach 25%.[68]

Fungal infections, especially those caused by *Candida* and *Aspergillus* spp, are serious and often result in fatal complications associated with HSCT. Fungi remain a serious cause of infection, particularly in allogeneic HSCT recipients, for up to 1 to 2 years following transplantation and may occur in as many as 10% of patients.[66,67,69] Mortality rates associated with invasive aspergillosis infections may be as high as 90%.[66,67,69,70]

In addition to bacterial and fungal infections, HSCT recipients are at risk for serious HSV infections including gingivostomatitis, esophagitis, genital lesions, and, rarely, pneumonia during the first month after transplant.[66,67,71] Clinical disease is more common in patients with serologic evidence (e.g., serum antibodies) of prior exposure and latent HSV infection pretransplant. Therefore, reactivation of latent disease during periods of immunosuppression is the most common etiology of HSV infection. Without prophylaxis, as many as 80% of HSV-seropositive patients experience mucocutaneous disease after intensive chemotherapy compared with less than 25% of seronegative patients.[66,67,71,72] HSV infections often coexist with candidal infection and mucositis secondary to chemotherapy, radiation, or both.[71,72] Acyclovir-resistant HSV infections occur following HSCT but are not common.[71] Painful swallowing associated with these conditions often makes it difficult for patients to take oral medications and maintain adequate nutritional intake. Because of the considerable morbidity associated with reactivation of HSV after transplantation, the HSV serologic status of patients should be determined prior to transplant.

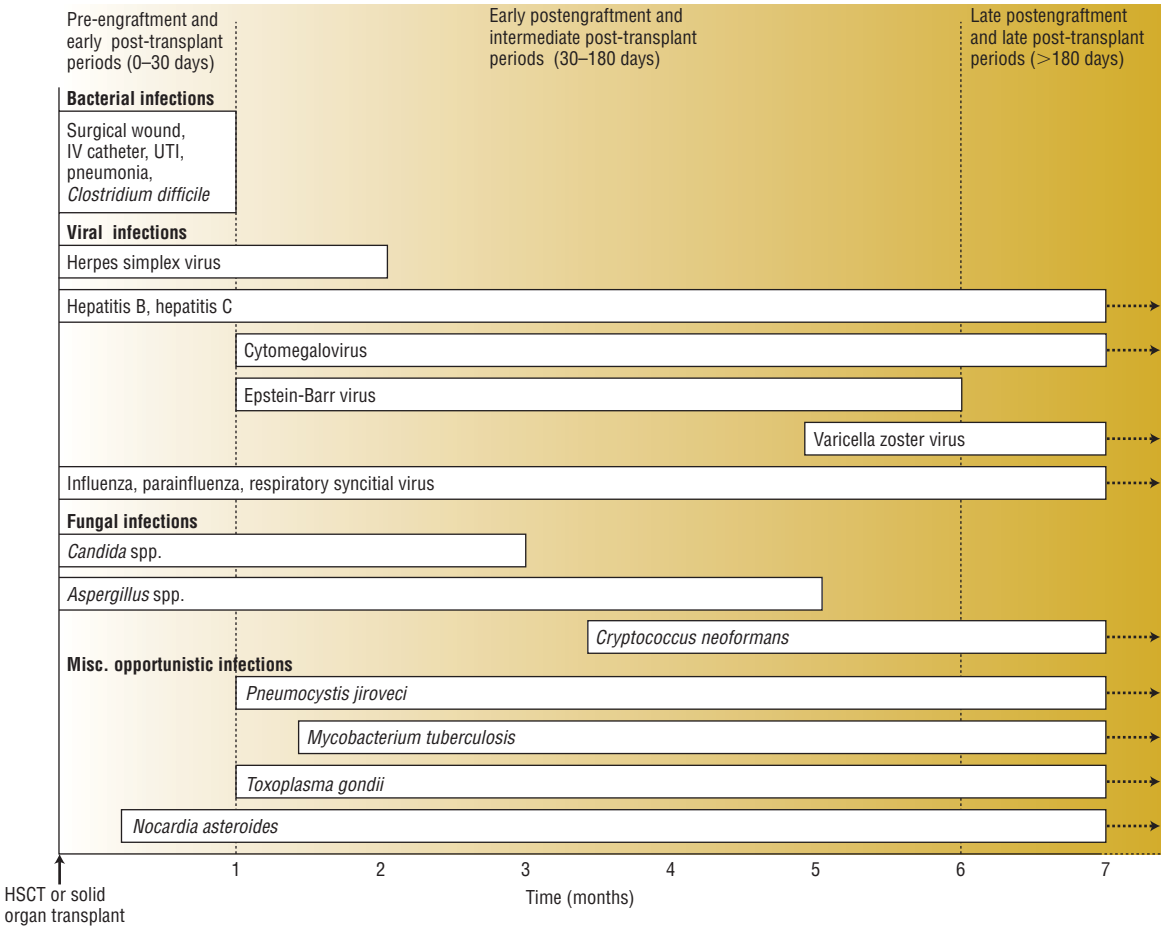

FIGURE 131-2. Timetable for the occurrence of infections in hematopoietic stem cell transplantation HSCT and solid organ-transplant patients. (IV, intravenous; UTI, urinary tract infection.)

HSCT recipients remain at high risk for infection after bone marrow engraftment has occurred.[66,67,71] Significant defects in neutrophil function and cell-mediated and humoral immunity, persisting for several months after transplantation, predispose patients to infectious complications. Acute and chronic GVHD also result in prolonged periods of immunosuppression and increased infection rates.

Bone marrow transplant patients are at high risk for Cytomegalovirus (CMV) infections during the early post-engraftment period. They range in severity from asymptomatic viral shedding (urine, throat, lungs) to life-threatening disseminated disease and interstitial pneumonia.[66,67,71,72]

As with HSV, patients seropositive for CMV before transplantation are at high risk for recurrent disease during periods of immunosuppression; approximately 70% of seropositive patients develop recurrent CMV disease after transplantation compared with only 3% of seronegative patients.[66,67,71,72] Other risk factors for CMV disease in HSCT patients include advanced age, human lymphocyte antigen mismatch, total-body irradiation, multiagent conditioning regimens, and presence of GVHD.[66,71] Patients without evidence of latent CMV infection (CMV seronegative) before transplantation may develop primary CMV disease after receiving bone marrow or blood products from CMV-seropositive donors. Although the typical onset of both primary and recurrent CMV infection is 1 to 2 months after transplantation, late-onset infections may occur more than 100 days after transplantation.[66,67,71,72] Patients receiving allogeneic transplants are at highest risk for CMV disease.[67,71,72]

The most serious clinical manifestation of CMV disease and the leading cause of infectious death in HSCT recipients is interstitial pneumonia, which is associated with an 85% mortality rate if left untreated.[66,67,71] This clinical syndrome manifests as fever, dyspnea, hypoxia, nonproductive cough, and diffuse pulmonary infiltrates. As many as 40% of allogeneic HSCT patients will develop interstitial pneumonia; of the patients with interstitial pneumonia, up to 40% of cases are caused by CMV.[67,71] Interstitial pneumonia also may result from other infectious (*P. jiroveci*, VZV) and noninfectious causes (pulmonary damage by radiation and chemotherapy).[67,71]

During the late post-engraftment period (beginning approximately 100 days after transplantation), infections remain a major problem in patients suffering from chronic GVHD. Additional immunosuppressive therapy for treatment of GVHD places these patients at added risk for infection. Infections common during the late post-engraftment period include those caused by encapsulated bacteria, such as *S. pneumoniae* and *H. influenzae*, fungi, and viruses, including CMV and VZV.[66,67,71] Patients not undergoing allogeneic transplantation or suffering from chronic GVHD generally have few infections in this period.

Up to 50% of all patients surviving up to 10 months after transplantation develop an infection caused by VZV.[67,71] Infection with VZV is most common in patients receiving allogeneic transplants with acute or chronic GVHD.[71,72] Both primary (varicella) or recurrent disease (herpes zoster) usually present as skin lesions, most of which remain contained to local areas; however, 30% to 45% of these infections may disseminate to other cutaneous areas or body organs, causing mortality as high as 50%.[71,72]

TREATMENT

Prophylaxis and Management of Infections in Recipients of HSCT

8 9 Goals of antimicrobial drug use in HSCT patients include (a) prevention of bacterial, fungal, viral, and protozoal infections during pre-engraftment and post-engraftment periods and (b) effective treatment of established infections. The overall goal of prophylaxis and treatment of infection in HSCT patients is prevention of infectious morbidity and mortality. These goals must be achieved at the lowest possible toxicity and cost. Prophylactic therapy should be specifically aimed at pathogens known to cause a high incidence of infection within the HSCT population, the specific institution, or both. In addition, prophylactic therapy should be limited to regimens proved to be effective through well-designed clinical trials.

Appropriate immunizations should be a primary consideration in the prevention of infections in HSCT recipients. Immunizations against common bacterial and viral pathogens are timed to avoid periods of severe immunosuppression following HSCT when the protective response to vaccination potentially would be decreased.[6] Current recommendations for immunization of HSCT patients include three doses each of diphtheria-pertussis-tetanus or diphtheria-tetanus, inactivated polio, conjugated *H. influenzae* type b, and hepatitis B vaccines at 12, 14, and 24 months after transplantation. The 23-valent pneumococcal vaccine should be administered at 12 and 24 months after HSCT, and the influenza vaccine should be administered prior to HSCT, resumed at least 6 months after transplantation, and continued for life. Family members, close contacts, and healthcare providers of HSCT patients also should be vaccinated annually against influenza. Finally, the measles-mumps-rubella vaccine should be administered no sooner than 24 months after HSCT when the patient is considered to be immunocompetent. The varicella vaccine is contraindicated for administration to HSCT patients owing to the live-attenuated nature of the product and the risk of VZV infection.[6]

BACTERIAL INFECTIONS

Prophylaxis of infections in HSCT patients is similar in many ways to that used in other neutropenic patients. Selective decontamination with oral antimicrobials is used commonly; considerations are the same as those discussed previously in the "Prophylaxis of Infections in Neutropenic Cancer Patients" section. Although some studies have shown decreased rates of bacteremia and other bacterial infections after HSCT, overall mortality rates were not reduced.[6,71] Therefore, routine use of prophylactic antibiotics in HSCT is still controversial. Fluoroquinolones have become the most frequently used agents, often combined with another agent (e.g., macrolides or rifampin), for enhanced gram-positive activity.[6,71] These regimens usually are started either within 72 hours of beginning the chemotherapy conditioning regimens or on the day of hematopoietic stem cell infusion and continued throughout the neutropenic period. Patients who become febrile while receiving prophylaxis should be managed according to general guidelines for febrile neutropenic patients.

Routine use of parenteral vancomycin for prophylactic therapy is not recommended. Prophylaxis with vancomycin has been studied because of the high incidence of gram-positive infections following transplantation. Vancomycin prophylaxis appears to decrease the overall incidence of gram-positive bacterial infections, number of days of empirical antimicrobial therapy, and cost of therapy.[6] However, important mortality benefits have not been demonstrated consistently, and there are significant concerns regarding the selection of vancomycin-intermediate *S. aureus* and vancomycin-resistant enterococci. Thus, prophylactic vancomycin use is not generally recommended except in institutions with high rates of MRSA infection among HSCT recipients.[6] There currently is no role for linezolid, quinupristin–dalfopristin, daptomycin, or telavancin as preferred antibiotics for management of infections in this population.

Antibiotic prophylaxis against bacterial infection is recommended in the late post-engraftment period (>100 days after transplantation) in certain high-risk patients, specifically allogeneic transplant recipients with chronic GVHD.[6] Antibiotics should be targeted against encapsulated bacteria such as *S. pneumoniae* and *H. influenzae* and should be selected based on local susceptibility patterns for these organisms. Patients receiving trimethoprim–sulfamethoxazole for prophylaxis of other opportunistic infections may be protected adequately and do not necessarily require an additional antibiotic.[6] Prophylaxis should be continued as long as the chronic GVHD is being actively treated.

VIRAL INFECTIONS

Prophylaxis of recurrent HSV infection is recommended for all HSV-seropositive patients undergoing HSCT.[6,71] Approximately 0% to 10% of HSV-seropositive patients receiving acyclovir experienced viral shedding, clinical symptoms of viral reactivation, or both compared with 60% to 80% of patients receiving placebo.[6,71] Acyclovir doses recommended for prophylaxis are 250 mg/m^2 (5 mg/kg) IV every 12 hours or 200 mg orally 3 times daily.[6,71] Intravenous therapy eventually is necessary in most patients because of the development of severe mucositis from conditioning regimens. Oral acyclovir is effective and considerably less expensive in patients who can take oral medications. Valacyclovir in doses of 500 to 1,000 mg/day is also commonly used and has replaced acyclovir as first-line therapy in many institutions.[6,71] Although the duration of antiviral prophylaxis differs among centers, acyclovir usually is started at the time of the conditioning regimen and continued until bone marrow engraftment or resolution of mucositis (approximately 30 days after HSCT).[6,71] In addition to preventing recurrence of HSV disease, acyclovir prophylaxis may reduce the incidence of CMV reactivation.[6] Patients developing active HSV or VZV infection should be treated with high-dose acyclovir (10 mg/kg IV every 8 hours).[71]

Although high-dose oral acyclovir given for 6 months after transplantation significantly reduces reactivation of VZV infections, routine use of long-term acyclovir is controversial and not generally recommended for this indication.[6,71] Patients who received HSCT within the previous 24 months or those more than 24 months after HSCT who have chronic GVHD or are undergoing immunosuppressive therapy should receive varicella-zoster immunoglobulin 625 units intramuscularly within 48 to 96 hours after close contact with persons with chickenpox or shingles for prevention of VZV-related disease.[6]

Acyclovir-resistant HSV has been reported occasionally in HSCT patients receiving acyclovir prophylaxis. Foscarnet is the drug of choice for treatment of acyclovir-resistant HSV. Foscarnet for HSV prophylaxis has not been well studied.[6,71]

Prevention of CMV disease has been studied extensively in HSCT patients and is a well-accepted indication for prophylaxis because of the high associated infectious morbidity and mortality. If possible, CMV-seronegative patients should receive donor cells and supportive blood products from seronegative donors only; however, CMV-seropositive patients are not at significant additional risk by receiving blood or donor cells from seropositive donors.[71] Although acyclovir has relatively poor in vitro activity against CMV, a

decrease in CMV infection and an improvement in overall survival were reported in HSV- and CMV-seropositive allogeneic HSCT recipients receiving IV acyclovir.[6]

Ganciclovir has been well studied for prophylaxis because of its superior activity against CMV compared with acyclovir.[6] Although administration of prophylactic ganciclovir to CMV-seropositive patients may significantly decrease the occurrence of CMV disease, studies have found no clear survival benefit, and ganciclovir-related bone marrow suppression frequently was problematic. Therefore, ganciclovir prophylaxis is only recommended routinely among allogeneic HSCT recipients for the first 100 days after transplantation.[6,71] The recommended dose of ganciclovir in these patients is 5 mg/kg IV every 12 hours for the first 5 to 7 days, followed by 5 to 6 mg/kg IV once daily 5 times per week until day 100 after HSCT.[6]

Perhaps a more appropriate role for ganciclovir is early or preemptive therapy, in which ganciclovir is administered at first isolation of CMV from the blood or bronchoalveolar lavage fluid. Detection of CMV can be accomplished by use of either a monoclonal antibody–based test for viral antigens or by detection of viral DNA through polymerase chain reaction (PCR)–based tests. Preemptive therapy has been evaluated in several studies.[71] It significantly reduced the occurrence of CMV disease (including CMV pneumonia) and improved survival significantly up to 180 days after transplantation.[71] Because CMV viremia and bronchoalveolar lavage cultures are highly predictive of subsequent CMV disease, preemptive ganciclovir therapy should be considered for autologous HSCT recipients within the first 100 days after transplantation or in allogeneic HSCT recipients at any time after transplantation.[6,71] The dose of ganciclovir for preemptive therapy is the same as that used for prophylaxis. Foscarnet can be used for either prophylaxis or preemptive therapy of CMV disease in patients intolerant of ganciclovir. The recommended foscarnet dose is 60 mg/kg IV every 12 hours for 7 days, followed by 90 to 120 mg/kg IV daily.[6,71] Oral valganciclovir 900 mg every 12 hours has not been well studied in the setting of HSCT.[73] However, oral valganciclovir has excellent pharmacokinetics and produces serum levels of ganciclovir which are at least similar to those achieved after intravenous administration.[74] Although not routinely recommended, valganciclovir is nevertheless used in many centers based on the favorable pharmacokinetic properties and convenience of oral dosing in certain patients.[71,73,74] CSFs are beneficial in this setting (Table 131–6), providing benefits similar to those noted in neutropenic patients with acquired immunodeficiency syndrome receiving ganciclovir therapy for CMV retinitis.[52,54]

Pharmacologic prevention of CMV disease with either intravenous immunoglobulin (IVIG) or CMV hyperimmune globulin (CMVIG) produced variable and inconclusive results.[75,76] The benefits of immunoglobulins for CMV prophylaxis in HSCT patients have not been demonstrated conclusively, and their use is not currently recommended.[75,76]

Ganciclovir is the drug of choice for treatment of active CMV infection in HSCT patients (see Table 131–5). Foscarnet also may be of benefit for treatment or prevention of infections in HSCT patients and may be used as an alternative to ganciclovir because of its relative lack of bone marrow toxicity. Foscarnet-related nephrotoxicity may be problematic, however, especially in the post-transplant period when patients may be receiving other nephrotoxic agents. Use of cidofovir is limited by the risk of nephrotoxicity, and this agent has not been well studied in HSCT patients.

Numerous single-agent treatments, such as vidarabine, interferon, and ganciclovir, have been used unsuccessfully as treatment for CMV pneumonitis. However, the combination of high-dose IVIG and ganciclovir may decrease the mortality of the syndrome from 85% to only 30% to 50%.[71,75,77] Ganciclovir plus hyperimmune CMVIG also is considered effective for treatment of CMV disease, although this regimen has not been studied as extensively in the HSCT population in a controlled fashion. The potential for ganciclovir-associated bone marrow suppression prior to marrow engraftment and in patients who are just recovering from granulocytopenia remains a concern, especially in patients with unstable renal function. Ganciclovir plus CMVIG is used widely as the treatment regimen of choice for severe or life-threatening CMV disease, this use being based on benefit-versus-risk considerations more than definitive clinical data. Ganciclovir plus IVIG also is used frequently, although CMVIG has replaced IVIG in many institutions.[75,77]

CLINICAL CONTROVERSY

Use of CMVIG for prophylaxis and/or treatment of CMV infections in HSCT and solid-organ transplantation patients is advocated by many clinicians. However, the clinical benefits of this expensive adjunct therapy have not been clearly demonstrated in these patients. Although CMVIG often is recommended in combination with ganciclovir for treatment of CMV pneumonia in transplant patients due to high mortality risk and few treatment options, its role in other types of infections is not clear.

FUNGAL INFECTIONS

Prophylaxis with antifungal agents is efficacious and generally recommended for prevention of mucocutaneous and disseminated candidal infections in high-risk HSCT patients (Table 131–2).[6,27,31,63,71,78–81] Patients specifically recommended for prophylaxis include all allogeneic transplant recipients and autologous recipients who are expected to have prolonged neutropenia, have received intensive conditioning regimens associated with extensive mucositis, or have recently received fludarabine.[6,27,31,63,71,78,79] Fluconazole 400 mg IV or orally once daily is the most commonly used regimen; it is started on the day of transplantation and continued until engraftment or resolution of neutropenia.[6,27,71,79] The variable activity of fluconazole against non-*albicans* species of *Candida* may be problematic in this population, as is lack of activity against *Aspergillus*.[31,63,32,79] Prophylaxis with fluconazole (as well as itraconazole), although effectively reducing colonization and infection with yeasts, has not been consistently demonstrated to reduce overall mortality or invasive infections such as aspergillosis in HSCT recipients.[31,63,71,78–81] Two newer antifungal agents have also shown efficacy in the prevention of fungal infections in patients undergoing HSCT. Micafungin 50 mg IV once daily was demonstrated to be more efficacious than fluconazole in the prevention of early-onset *Candida* infections in patients with neutropenia prior to engraftment. Posaconazole 200 mg suspension three times daily was also more effective than fluconazole 400 mg orally once daily in the late prevention of invasive *Aspergillus* and other fungal infections in HSCT patients with GVHD. Fluconazole, posaconazole, and micafungin are all recommended for prophylaxis of fungal infections in HSCT. In high-risk HSCT patients with GVHD, posaconazole is the preferred agent with micafungin recommended as an alternative agent along with itraconazole (Table 131–2).[31,33,63,78–80]

Fluconazole, posaconazole, and other azole antifungals may cause significant elevations in serum cyclosporine concentrations and pre-dispose to cyclosporine toxicities; this interaction should be monitored closely in HSCT patients receiving these agents concurrently.[27,33,80]

PROTOZOAL INFECTIONS

Pulmonary infection with *P. jiroveci* is a relatively infrequent complication of HSCT. However, mortality rates in this population are approximately 60% and are especially high in patients with GVHD.[6,67] Prophylactic trimethoprim–sulfamethoxazole (one double-strength tablet 3 times per week or one single-strength tablet daily) is given commonly in this setting. Toxoplasmosis is not a common infection in HSCT patients but is associated with mortality rates of approximately 70%.[82] Toxoplasmosis should be prevented by trimethoprim–sulfamethoxazole prophylaxis.[6]

USE OF COLONY-STIMULATING FACTORS

A number of studies have evaluated the use of filgrastim, pegfilgrastim, and sargramostim in HSCT patients in an effort to speed bone marrow recovery, reduce the period of neutropenia, and decrease infectious complications. CSFs appear effective as well as safe following autologous transplantation, although increased rates of GVHD and mortality have been reported with use of CSFs following allogeneic transplantation.[52] The use of CSFs is now routinely recommended to mobilize blood progenitor cells and reduce the period of neutropenia in autologous transplants (Table 131–6).[52,54]

EVALUATION OF THERAPEUTIC OUTCOMES

⑩ Close monitoring of HSCT patients, including clinical and laboratory data, is essential for early detection and treatment of infectious complications. In addition, because many of the drugs commonly used in this setting (e.g., ganciclovir, amphotericin B, and trimethoprim–sulfamethoxazole) have significant toxicity potential in HSCT patients, careful attention must be paid to prevention and management of drug-related adverse effects. Monitoring parameters related to specific types of infections (e.g., pneumonia and urinary tract infections) should be applied as appropriate. The reader is referred to other chapters within this book for more specific information.

INFECTIONS IN SOLID-ORGAN TRANSPLANT RECIPIENTS

Since the introduction of cyclosporine in 1980, solid-organ transplantation has become an established mode of treatment for end-stage diseases of the heart, lungs, kidney, liver, pancreas, and small bowel. Patient and allograft survival rates greatly exceed those of the past. Reasons for improved survival include continuous improvements in immunosuppressive drug therapy, candidate selection, and transplant surgery techniques and more experience in the management of complications (including infection) in these patients. Despite advances in diagnostic techniques and antimicrobial therapy, infectious complications remain important causes of morbidity and mortality after solid-organ transplantation.

RISK FACTORS

① Many of the risk factors for infection are present in solid-organ transplant patients (see Table 131–1). The most important risk factor in this population is immunosuppressive drug therapy for prevention and treatment of allograft rejection. Risk of infection depends on specific immunosuppressive drug regimens as well as the intensity (dose) and duration of immunosuppression. Most opportunistic infections in transplant patients occur during the first 6 months after transplantation, when the intensity and total cumulative doses of immunosuppressive therapy are very high.[83,84]

Immunosuppressive drugs, often in escalated doses, are used to treat episodes of graft rejection. Drugs used to treat rejection include immunoglobulins directed against T cells (e.g., antithymocyte globulin), murine monoclonal antibodies (muromonab), antibodies against interleukin 2 receptors (daclizumab and basiliximab), T-cell–depleting antibodies (alemtuzumab), and high-dose IV or oral corticosteroids. Rejection episodes often occur during the post-transplant period when the overall cumulative dose or net state of immunosuppression is highest (2–4 months post-transplant).[83,85] Therefore, patients already at risk for infection are placed at even higher risk if additional immunosuppressive therapy is needed to treat one or more episodes of graft rejection. Immunosuppressive drug therapy must be evaluated carefully when infections occur because, in many cases, immunosuppression may have to be reduced to allow patients to survive the infectious episode, at the expense of increased risk of graft rejection. Risk of increased infectious complications from immunosuppressive therapy used to treat rejection episodes is determined, at least in part, by the specific therapy used.[83–85]

ETIOLOGY

② As with cancer patients, microorganisms infecting solid-organ transplant patients are present before transplantation or are acquired from exogenous sources. All transplant recipients are at risk for mucocutaneous candidiasis from species colonizing body sites. Invasive fungal infection is less common following kidney and pancreas transplantation (5%–15%) but also may occur in 30% to 60% of heart, lung, liver, and small bowel transplant recipients. Rates are highest following liver and small bowel transplantation and are associated with mortality rates up to 60% to 70%.[83,86,87] Approximately 50% to 90% of all systemic fungal infections in transplant recipients are caused by *Candida* spp.[83,86,87] Abdominal surgery, especially the more complex procedures required for liver and small bowel transplantation, predispose patients to serious fungal disease, most likely as a consequence of entering an area already colonized with *Candida* spp.[86] Lung and heart transplant recipients are particularly at risk for invasive aspergillosis; these infections may occur in up to 10% of patients.[86] Liver and lung transplant recipients are at high risk for serious gram-negative bacterial infections as a result of the technically difficult surgical procedures.[83]

Organisms present as latent tissue infections may reactivate and cause clinical disease after transplantation with administration of immunosuppressive drug therapy. Disease resulting from infection reactivation has been noted with viral (HSV-1 and HSV-2, CMV, VZV, Epstein-Barr virus), protozoal *(Toxoplasma gondii, P. jiroveci)*, and mycobacterial *(Mycobacterium tuberculosis)* pathogens.[88,89] Serologic or immunologic tests are performed prior to transplantation to assess the risk for infection because of reactivation and identify other subclinical infections (e.g., hepatitis B, hepatitis C, *Legionella*). Many patients with reactivated disease have no clinical symptoms; often the only evidence of active infection is a rise in antibody titer from the pre-transplant baseline, positive culture, or histologic evidence. Reactivation of latent infection may result in severe life-threatening disease in immunosuppressed hosts.[89]

Exogenous sources of infection in transplant patients include environmental contamination and transmission of microorganisms via transplanted organs and blood products. Environmental sources of infection are similar to those noted in other immunocompromised hosts, such as cancer patients. Airborne pathogens, especially fungi, such as *Aspergillus* and *Cryptococcus neoformans*, may cause infections in transplant patients; this is thought to be a direct cause of increased *Aspergillus* infections among lung transplant patients.[83,86] Transplant patients are at risk for common nosocomial infections and infections occurring as hospital outbreaks (*P. aeruginosa*, *Acinetobacter*, and *Legionella*). Optimal prevention

and management of nosocomial infections in transplant patients require knowledge of the current epidemiology of infections and susceptibility patterns in the institution.

Infections transmitted via donor organs or blood products are major causes of morbidity and mortality in transplant patients and may include HSV, *T. gondii*, and hepatitis B and C. The most important infections transmitted from the donor, however, are caused by CMV. These infections may cause serious disease (e.g., pneumonia, hepatitis, hematologic disorders, and chorioretinitis). They also may predispose patients to other opportunistic infections and contribute to acute and chronic allograft dysfunction or rejection, post-transplant lymphoproliferative disorders, and cardiac complications and atherosclerosis in heart transplant recipients.[83,90] In contrast to reactivation disease, transplant patients contracting primary CMV disease are at increased risk for serious life-threatening infections.[83,91–93] The most important source of primary CMV infection in transplant patients is the donor organ. Efforts are made to avoid transplanting organs from CMV-seropositive donors into CMV-seronegative recipients because of the potentially severe consequences. With the relative scarcity of suitable organs and the rapidity with which transplant decisions often must be made, however, this is not always possible. The consequences of transplanting an organ from a CMV-seropositive donor into an already CMV-seropositive recipient are less clear. CMV reinfection (as well as reactivation) syndromes may occur in these patients.[83,84,93] In addition to transmission from donor organs, primary CMV disease may be transmitted from seropositive blood products, although this is a much less common mode of transmission.

Organs from donors seropositive for *T. gondii* or HSV generally are not withheld from seronegative patients. Organs from known HIV-infected donors, however, are not used for transplantation. Asymptomatic HIV-seropositive individuals with $CD4^+$ lymphocyte count greater than 400 cells/mm^3 may be considered for solid-organ transplantation (as well as HSCT) without prohibitively high risk for acceleration of HIV disease.[92,94] However, this practice is not widespread because of the shortage of donor organs. The impact of protease inhibitors and highly active antiretroviral therapy on long-term outcome of HIV-infected patients following transplantation is not precisely known but is believed to have improved the overall feasibility of transplanting these individuals.[94]

Table 131–5 provides information on microbiology, clinical presentation, and treatment of infections in HSCT and solid-organ transplant recipients. Although opportunistic viral, fungal, and protozoal infections may occur commonly, bacterial infections remain the most frequent infectious complications after transplantation in all allograft recipients.

TIMING OF INFECTIONS AFTER TRANSPLANTATION

Although risk of infection with specific pathogens varies with the type of transplant, the time course of infections is similar in all transplant recipients. The overall risk of infection is greatest during the first 6 months after transplantation, when the greatest number of risk factors are present. Both daily and cumulative doses of immunosuppressive drugs are at high levels, and additional agents may be necessary for treatment of acute rejection episodes.[83,84]

As with HSCT, the overall time course for infections can be divided into three general periods after transplantation (see Fig. 131–2). During the early post-transplant period (within the first month after transplantation), patients are at risk for infections already present and brought forward from the pre-transplant period (e.g., hepatitis B); postoperative infections, such as surgical wound and catheter infections; infection resulting from colonized donor organs (pneumonia following lung transplant); and reactivation of HSV.[83,84,89] In the intermediate post-transplant period (2–6 months after transplant), risk is highest for viral infections, including CMV, Epstein-Barr virus, and hepatitis B and C. The combination of these "immunomodulating" viruses plus sustained immunosuppressive therapy leads to a high risk for opportunistic infections with pathogens such as *P. jiroveci*, *Aspergillus*, and *Nocardia asteroides*.[83,84,86,89] In the late post-transplant period (>6 months after transplant), patients are at risk for persistent infections (particularly viral) from earlier post-transplant periods, reactivation of VZV and *C neoformans*, and routine infections affecting the general population.[83] In addition, patients who required additional immunosuppression therapy for acute or chronic rejection are at continued high risk for opportunistic infections *(Aspergillus* and *P. jiroveci)*.[83,84,86] Although Figure 131–2 illustrates infection patterns common to all solid-organ transplants, the relative incidence and importance of a particular pathogen vary according to the type of transplant.

TYPES OF INFECTIONS AND CLINICAL PRESENTATION

⑩ Transplant patients are at risk for infections occurring at a variety of sites, including skin, surgical wound, urinary tract, lungs, blood, abdomen, and CNS. However, most infections occur at or near the site of the transplanted organ. For example, heart transplant and heart and lung transplant recipients most often are infected within the lungs or thoracic cavity. Urinary tract infections remain an important cause of morbidity in renal transplant patients, especially in the early post-transplant period. Administration of prophylactic antibiotics (e.g., trimethoprim–sulfamethoxazole) to these patients has reduced the incidence and severity of urinary tract infections.[83,84] Serious bacterial and fungal infections originating from the abdomen and GI tract are most common after liver transplantation and are related to variables such as length of surgery and surgical procedures performed. Risk of bacteremia, usually originating from the gut, is highest in liver transplant patients. Renal transplant recipients are at the lowest risk for infections and infectious deaths, whereas patients receiving heart, lung, and liver transplants are at the highest risk for infection-related morbidity and mortality.[83,84,86]

CLINICAL PRESENTATION OF INFECTIONS IN SOLID-ORGAN TRANSPLANT PATIENTS

General

- Because transplant patients are at high risk for serious infections, frequent (at least daily), careful clinical assessments must be performed to search for evidence of infection.
- Clinical presentation of infection is variable and depends on the type and site of infection, type of transplant, time after transplantation, immune status of the host, and dose and duration of immunosuppressive therapy.
- Primary viral disease usually is more symptomatic and severe than disease caused by reactivation.
- Physical assessment should include examination of all common sites of infection, including mouth/pharynx, nose and sinuses, respiratory tract, GI tract, urinary tract, skin, soft tissues, perineum, and intravascular catheter insertion sites.

Symptoms

- Usual signs and symptoms of infection may be absent or altered in patients receiving intensive immunosuppressive regimens owing to an inability to mount a typical inflammatory response (e.g., no infiltrate on chest x-ray film, urinary tract infection without pyuria).
- Pain may be present at infection site(s).

Signs

- Fever is the single most important clinical sign indicating the presence of infection. Other causes of fever unrelated to infection in this patient population include reactions to blood products, drugs, embolic events, and ischemic injury.
- Usual signs of infection may be absent or altered.
- Signs of allograft dysfunction may be related to infection. Distinguishing fever caused by allograft rejection from that caused by infection often is difficult and frequently requires allograft biopsy.

Laboratory Tests

- Blood cultures (at least two sets, including vascular access devices) for bacteria and fungi; cultures of other suspected or potential infection sites (urine, lungs, surgical wounds, and soft tissue infections).
- Other cultures should be obtained as clinically indicated according to the presence of signs or symptoms.
- Complete blood count and chemistries should be obtained frequently to monitor allograft function, plan supportive care, guide drug dosing, and assess patient's overall status.
- Surveillance cultures for CMV and HSV may be useful during first 3 months after transplantation for early detection of infection.

Other Diagnostic Tests

- Chest x-ray film
- Aspiration, biopsy of skin lesions
- Other diagnostic tests as indicated clinically on the basis of physical examination and other assessments

In contrast to febrile neutropenic patients, the threshold for initiating empirical antimicrobial therapy is higher in febrile transplant patients. Appropriate therapy for the large numbers of pathogens that may cause infections in transplant patients varies greatly from organism to organism (Table 131–5). Therefore, careful attempts at definitive diagnosis of suspected infections must be made. If comprehensive workup reveals no source of infection, careful observation of the febrile transplant patient (rather than empirical therapy) is common practice. Surveillance cultures may be useful during the first 3 months for detecting CMV and HSV infections.[83,86,91,92,95] Management and monitoring of documented infections are similar to that in other types of patients.

Prevention of Infection in Solid-Organ Transplantation

8 The goals of antimicrobial drug use in solid-organ transplant recipients are (a) prevention of infectious complications in the immediate postoperative period, (b) prevention of late infectious complications associated with prolonged periods of immunosuppression, and (c) effective treatment of established infections in order to prevent graft dysfunction and rejection and decrease patient morbidity and mortality. All of these goals must be achieved at the lowest possible toxicity and cost.

Prevention of infection in the transplant patient can be accomplished in a number of ways. First, risk of environmental contamination should be minimized.[96] Patients should be protected from institutional infectious outbreaks. Transplant patients should receive the pneumococcal vaccine once and the influenza vaccine yearly; however, their immunologic responses to these vaccines may be blunted by immunosuppressive therapy.[83]

Because the most important source of primary CMV disease is an infected donor organ, CMV-seronegative patients should not receive organs or blood products from seropositive donors if possible. A number of pharmacologic strategies have been studied in an attempt to prevent CMV infection. Prophylactic ganciclovir (administered as either 5 mg/kg IV every 12 hours or oral valganciclovir in doses ranging from 900 mg once daily to 1,000 mg 3 times daily) is effective in reducing the incidence of both primary and reactivated CMV disease in solid-organ transplantation.[73,77,83,84,90–93] Ganciclovir prophylaxis also may reduce reactivation of CMV disease significantly in seropositive patients receiving antithymocyte globulin or muromonab for treatment of acute rejection.[84,92,93] High-dose oral acyclovir effectively reduces the incidence of CMV infection and disease following renal transplantation. However, acyclovir is less efficacious in high-risk renal transplant patients (donor positive, recipient negative for CMV serum antibodies) and other nonrenal transplant types.[83,84,90–93,97] Preemptive ganciclovir or valganciclovir (initiated after actual isolation of CMV from blood, urine, bronchoalveolar lavage fluid, or other site) is more effective than acyclovir in preventing both primary and reactivation disease in liver transplant recipients. Preemptive ganciclovir effectively prevents CMV disease in other types of solid-organ transplants as well.[91,92,95] Ganciclovir-related bone marrow suppression is not as problematic in solid-organ transplant recipients as in HSCT patients; most studies report the drug is reasonably well tolerated.[77,83,91,92,95,97]

Whether prophylaxis or preemptive therapy is the best approach to preventing CMV disease is controversial.[77,83,91–93,95] Prophylaxis is effective and easy to administer without the need for careful discrimination among suitable patients. However, universal prophylaxis results in unnecessary exposure of low-risk individuals to adverse effects of drugs, and there are concerns that prolonged exposure may increase the risk of viral resistance to drugs.[91,92,97] Preemptive therapy is effective and results in exposure of fewer patients to drugs. However, this strategy requires the availability and routine use of sensitive and specific diagnostic tests in order to identify high-risk individuals at an early stage of CMV infection. Although currently available PCR-based methods make this latter consideration less of an issue, PCR testing is not available at all centers. Prophylactic therapy should be used primarily in patients at highest risk of disease (i.e., seronegative patients receiving organs from seropositive donors), whereas other lower-risk patients should receive only preemptive therapy.[83,91,92,95] However, these recommendations are not universally accepted or practiced.

CMVIG is valuable in decreasing the incidence and severity of CMV disease following kidney, heart, lung, and liver transplantation.[77,83,91] Although prophylaxis with CMVIG has been strongly recommended for CMV-seronegative transplant recipients receiving organs from seropositive donors, the benefits of CMVIG relative to other therapies (e.g., prophylactic or preemptive ganciclovir) are not well known, and available studies have conflicting results. Whether the combination of CMVIG plus ganciclovir offers advantages over the use of either agent alone, either for primary prophylaxis or for treatment of established CMV disease, in solid-organ transplantation is unclear.[83,91] However, some authorities recommend use of CMVIG in combination with ganciclovir for treatment of severe, life-threatening CMV pneumonitis in solid-organ transplant recipients.[75,77]

Although use of prophylactic acyclovir in HSV-seropositive patients undergoing HSCT is well accepted, prophylaxis in solid-organ transplant recipients remains controversial. Reactivation disease caused by HSV occurs in approximately 25% of HSV-seropositive patients who are not receiving prophylaxis.[83] Oral or genital mucocutaneous disease is the most common presentation, but HSV pneumonitis also is seen occasionally and is associated

with a mortality rate of approximately 75%.[83] Acyclovir is used at some centers because of the high incidence of clinical HSV infection, including pneumonias, after transplantation.

Prophylactic antimicrobial agents are of benefit to transplant patients in certain clinical situations. Antibiotic prophylaxis, with agents such as cefazolin started perioperatively and continued for less than 24 hours, is considered to reduce wound infection rates effectively following renal transplantation.[83,96] Although the benefits of perioperative prophylaxis have not been well demonstrated in other types of transplantation procedures, surgical prophylaxis usually is considered mandatory for liver, heart, lung, or small bowel transplant patients because of the high risk of perioperative bacterial infections.[83,96] Pulmonary infections are particularly common in lung and heart-lung transplant recipients. They often are caused by bacteria colonizing the airways of the diseased organs prior to transplantation. Therefore, perioperative antibiotics for lung and heart and lung procedures often are selected based on pre-transplant sputum cultures.[83,96] In addition, post-transplant antibiotic prophylaxis is effective in decreasing the number of bacterial infections in renal transplant patients. Prophylactic trimethoprim–sulfamethoxazole traditionally has been used because it is inexpensive and well tolerated; other antibiotics, such as the fluoroquinolones, also have been evaluated.[83] Administration of oral low-dose trimethoprim–sulfamethoxazole (one double-strength tablet daily) for 6 to 12 months for prevention of *P. jiroveci* infection following heart and lung transplantation is common, although the efficacy and optimal duration are somewhat controversial.[83,98] Selective bowel decontamination with nonabsorbable antibiotics in combination with a low-bacterial diet (no fresh fruits and vegetables) effectively reduces oropharyngeal and GI colonization with gram-negative aerobes and *Candida* in liver transplant patients. However, selective bowel contamination is less efficacious when administered for a period of less than 1 week prior to transplantation.[96] Because liver transplantation usually is performed without advance notice as organs become emergently available, the practice of selective bowel decontamination remains controversial and is not recommended routinely.[83,96]

Because immunosuppressed transplant recipients are at risk for mucocutaneous fungal infections, prophylactic oral or topical antifungal agents may be indicated in these patients. Liver, pancreas, and small bowel transplant recipients are clearly at high risk for invasive fungal infections and should receive prophylaxis with fluconazole (400 mg/day).[27,83,86,99] Prophylaxis has also been suggested for lung and heart-lung transplant recipients with high-dose fluconazole, itraconazole, or voriconazole; however, data supporting either this general recommendation or choice of specific agent are lacking.[27,86] Concentrations of immunosuppressant drugs should be monitored closely in transplant patients receiving azole-type antifungal agents (fluconazole, itraconazole, voriconazole).

Transplant patients, especially heart and heart and lung recipients, without serologic evidence of prior exposure to *T. gondii* who receive organs from seropositive donors are at high risk for toxoplasmosis.[83] Many of these patients will be receiving trimethoprim–sulfamethoxazole for prophylaxis of *P. jiroveci* infection; this agent will also provide effective prophylaxis against *T. gondii* as well as *N. asteroides.* Although prophylaxis is not given routinely at all centers, this therapy may be justified in high-risk patients because of the delays in diagnosis and serious infections associated with toxoplasmosis.[83]

EVALUATION OF THERAPEUTIC OUTCOMES

Close monitoring of transplant recipients, including both clinical and laboratory data, is essential for early detection and treatment of potentially severe opportunistic infections.

CHAPTER 132

Antimicrobial Prophylaxis in Surgery

SALMAAN KANJI

KEY CONCEPTS

1. Prophylactic antibiotic therapy differs from presumptive and therapeutic antibiotic therapy in that the latter two involve treatment regimens for documented or presumed infections, whereas the goal of prophylactic therapy is to prevent infections in high-risk patients or procedures.
2. The risk of a surgical site infection (SSI) is determined from both the type of surgery and the patient-specific risk factors; however, most commonly used classification systems account for only procedure-related risk factors.
3. The timing of antimicrobial prophylaxis is of paramount importance. Antibiotics should be administered within 1 hour before surgery to ensure adequate drug levels at the surgical site prior to the initial incision.
4. Antimicrobial agents with short half-lives (e.g., cefazolin) may require intraoperative redosing during long (>3 hours) procedures.
5. The type of surgery, intrinsic patient risk factors, most commonly identified pathogenic organisms, institutional antimicrobial resistance patterns, and cost must be considered when choosing an antimicrobial agent for prophylaxis.
6. Single-dose prophylaxis is appropriate for many types of surgery. First-generation cephalosporins (e.g., cefazolin) are the mainstay for prophylaxis in most surgical procedures because of their spectrum of activity, safety, and cost.
7. Vancomycin as a prophylactic agent should be limited to patients with a documented history of life-threatening β-lactam hypersensitivity or those in whom the incidence of infections with organisms resistant to cefazolin (e.g., methicillin-resistant *Staphylococcus aureus*) is high enough to justify use.

According to the National Center for Health Statistics, some 46 million surgical procedures are performed annually in the United States, the majority of which are done in an outpatient setting.[1] Infection is the most common complication of surgery.[2] Surgical site infections (SSIs) occur in ~3% to 6% of patients and prolong hospitalization by an average of 7 days at a direct annual cost of $5 billion to $10 billion.[3,4] SSIs are the third (14–16%) most frequent cause of nosocomial infections among hospitalized patients and the primary (40%) cause of nosocomial infection in surgical patients.[3] Prophylactic administration of antibiotics decreases the risk of infection after many surgical procedures and represents an important component of care for this population.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Antibiotics administered prior to the contamination of previously sterile tissues or fluids are called prophylactic antibiotics. The goal of therapy is to prevent an infection from developing. Although eradication of distal (preexisting, unrelated to surgery) infections lowers the risk for subsequent postoperative infections, it does not per se constitute a prophylactic regimen. In fact, surgical prophylaxis often is prescribed concurrently under these circumstances because of important antimicrobial spectrum- and timing-related concerns. Both SSIs and infections not directly related to the surgical site (e.g., urinary tract infections and pneumonia) are termed *nosocomial*. Prevention of hospital-acquired infections is a major goal of antibiotic prophylaxis.

1 Presumptive antibiotic therapy is administered when an infection is suspected but not yet proven. Clinical scenarios where presumptive therapy is used commonly include acute cholecystitis, open compound fractures, and acute appendicitis of less than 24 hours' duration. In these situations, if signs of perforation or infection are absent during surgery, then routine prophylactic treatment rather than presumptive therapy is warranted. An operative finding of a gangrenous gallbladder or a perforated appendix, however, is suggestive of an established infectious process, and a therapeutic antibiotic regimen is required.[3]

According to the Centers for Disease Control and Prevention's (CDC) National Nosocomial Infections Surveillance System (NNIS),[3] SSIs can be categorized as either incisional (e.g., cellulitis of the incision site) or organ/space (e.g., meningitis; Fig. 132–1). Incisional SSIs are subcategorized into superficial (involving only the skin or subcutaneous tissue) and deep (fascial and muscle layers) infections. Organ/space SSIs can involve any anatomic area other than the incision site. For example, a patient who develops bacterial peritonitis after bowel surgery has an organ/space SSI. By definition, SSIs must occur within 30 days of surgery. If a prosthetic implant is involved, a deep incisional or organ/space SSI can be reported up to 1 year from the date of surgery. Although microbiologic testing of surgical drainage material or sites may help to guide care, the specificity of a negative culture is poor and generally does not rule out an SSI.[3]

RISK FACTORS FOR SURGICAL SITE INFECTIONS

2 SSI incidence depends on both procedure- and patient-related factors. Traditionally, the risk for SSIs has been stratified by surgical procedure in a classification system developed by the National

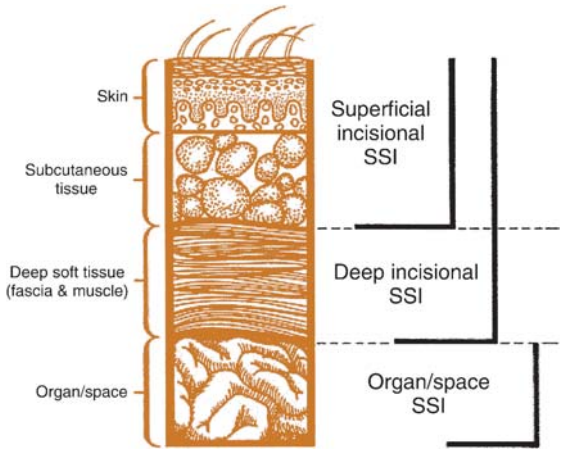

FIGURE 132-1. Cross section of abdominal wall depicting Centers for Disease Control and Prevention classifications of surgical site infections (SSI). *(Reprinted from Mangram AJ, Horan TC, Pearson ML, et al. Guideline for prevention of surgical site infection. Am J Infect Control 1999;27:97–132 with permission from Elsevier. Centers for Disease Control and Prevention (CDC) Hospital Infection Control Practices Advisory Committee, Copyright 1999, with permission from the Association for Professionals in Infection Control and Epidemiology.)*

Research Council (NRC; Table 132–1).[5] The NRC classification system proposes that the risk of an SSI depends on the microbiology of the surgical site, the presence of a preexisting infection, the likelihood of contaminating previously sterile tissue during surgery, and the events during and after surgery.[5,6] A patient's NRC procedure classification is the primary determinant of whether antibiotic prophylaxis is warranted. However, because a patient's NRC wound classification is influenced by surgical findings (e.g., gangrenous gallbladder) and perioperative events (e.g., major technique breaks), categorization generally occurs intraoperatively.[7]

INHERENT PATIENT RISK

The NRC classification system does not account for the influence of underlying patient risk factors for SSI development, instead categorizing the risks for SSIs simply based on a specific surgical procedure. Disease states and conditions known to increase SSI risk are listed in Table 132–2. Preexisting distal infections increase SSI rates and should be resolved prior to surgery whenever possible. Diabetic patients have an increased risk for SSIs, especially those with uncontrolled perioperative blood sugars. Preoperative smoking has been identified as an independent risk factor for SSI because of the deleterious effects of nicotine on wound healing. Preoperative immunosuppression, including corticosteroid use, may increase infection risk. Patients co-infected with human immunodeficiency virus (HIV) and hepatitis C are at approximately double the risk of SSI as the general population.[8] Malnutrition is a well-described risk factor for postoperative complications, including SSI, impaired wound and colonic anastomosis healing, and prolonged hospital stay. Although enteral feeding during the perioperative period can reduce bacterial translocation by maintaining the integrity of the intestinal mucosa, nutritional supplementation does not decrease the incidence of infection.[9]

Colonization of the nares with *Staphylococcus aureus* is a well-described SSI risk factor.[3] Although intranasal application of mupirocin ointment reduces the rate of nasal carriage of *S. aureus,* one large, randomized, double-blind study of 4,030 surgical patients found that prophylactic intranasal mupirocin did not reduce the rate of *S. aureus* SSI, although it did reduce the rate of nosocomial *S. aureus* infections among patients who were *S. aureus* carriers.[10] Other factors shown to increase the risk of SSI are age, length of preoperative hospital stay, and obesity.[3]

IDENTIFYING SSI RISK

Two large epidemiologic studies have objectively quantified SSI risk based on specific patient- and procedure-related factors. The Study on the Efficacy of Nosocomial Infection Control (SENIC) analyzed more than 100,000 surgery cases to identify and validate risk factors for SSI.[11] Abdominal operations, operations lasting longer than 2 hours, contaminated or "dirty" procedures (as per NRC classification), and more than three underlying medical diagnoses each was associated with an increased incidence of SSI. When NRC classification was stratified by number of SENIC risk factors present, SSI incidence varied by as much as a factor of 15 within the same NRC operative category (Table 132–3).[12]

In a subsequent analysis of more than 84,000 surgical cases, the NNIS attempted to simplify and refine the SENIC system by quantifying intrinsic patient risk using the American Society of Anesthesiologists' (ASA) preoperative assessment score (Table 132–4).[14,15] An ASA score ≥3 was a strong predictor for the development of an SSI. Other factors associated with increased SSI incidence are contaminated or "dirty" operations (NRC criteria) and surgical procedures lasting longer than average. As in the SENIC study, the SSI rate was linked to the number of risk factors present and varied considerably within NRC class. The NNIS basic SSI risk index is composed of the following criteria: ASA score = 3, 4, or 5; wound class; and duration of surgery. Overall, for 34 of the 44 NNIS procedure categories, SSI rates increased proportionally

TABLE 132-1 National Research Council Wound Classification, Risk of Surgical Site Infection, and Indication for Antibiotics

	SSI Rate (%)			
Classification	**Preoperative Antibiotics**	**No Preoperative Antibiotics**	**Criteria**	**Antibiotics**
Clean	5.1	0.8	No acute inflammation or transection of GI, oropharyngeal, genitourinary, biliary, or respiratory tracts; elective case, no technique break	Not indicated unless high-risk procedure[a]
Clean–contaminated	10.1	1.3	Controlled opening of aforementioned tracts with minimal spillage/minor technique break; clean procedures performed emergently or with major technique breaks	Prophylactic antibiotics indicated
Contaminated	21.9	10.2	Acute, nonpurulent inflammation present; major spillage/technique break during clean–contaminated procedure	Prophylactic antibiotics indicated
Dirty	N/A	N/A	Obvious preexisting infection present (abscess, pus, or necrotic tissue present)	Therapeutic antibiotics required

[a]High-risk procedures include implantation of prosthetic materials and other procedures where surgical site infection is associated with high morbidity (see text).
GI = gastrointestinal; N/A = not applicable; SSI = surgical site infection.

with the number of risk factors present.[13] The SSI rate was generally lower when the procedure was done laparoscopically.

Although evidence-based recommendations for antimicrobial prophylaxis during surgery are best established using the results of randomized clinical trials, many studies have small sample sizes and do not stratify patients according to overall SSI risk. Future studies, particularly those involving clean procedures, should be stratified by SSI risk so that the subset of high-risk patients who might benefit the most from prophylaxis is clearly established.

BACTERIOLOGY

The most important consideration when choosing antibiotic prophylaxis is the bacteriology of the surgical site. Organisms involved in an SSI are acquired by one of two ways: endogenously (from the patient's own normal flora) or exogenously (from contamination during the surgical procedure). Based on the type and anatomic location of the procedure and the NRC classification (see Table 132–1), resident flora can be predicted and appropriate antibiotic choices made. According to NNIS data, *S. aureus,* coagulase-negative staphylococci, enterococci, *Escherichia coli,* and *Pseudomonas aeruginosa* are the pathogens most commonly isolated (Table 132–5).[14] With the widespread use of broad-spectrum antibiotics, however, *Candida* species and methicillin-resistant *S. aureus* (MRSA) are becoming more prevalent.[14]

Factors affecting the ability of an organism to induce an SSI depend on organism count, organism virulence, and host immunocompetency. Organisms in the commensal flora generally are not pathogenic. These organisms often serve the host as a form of protection against invasive organisms that otherwise would colonize the surgical site. Opportunistic organisms usually are kept in check by normal flora and rarely are problematic unless they are present in large numbers. The loss of normal flora through the use of broad-spectrum antibiotics can destabilize homeostasis, allowing pathogenic bacteria to proliferate and infection to occur.[4]

Normal flora translocated to a normally sterile tissue site or fluid during a surgical procedure can become pathogenic. For example, *S. aureus* or *Staphylococcus epidermidis* may be translocated from the surface of the skin to deeper tissues or *E. coli* from the colon to the peritoneal cavity, bloodstream, or urinary tract. Studies in animals and healthy volunteers have shown bacterial virulence to be an important determinant in the development of secondary infections.[16,17] Whereas more than one million *S. aureus* per square centimeter or gram of tissue are required to produce infection in animals, less than 100,000 *Streptococcus pyogenes* per square centimeter or gram of tissue are required at the same site.[17,18]

Impaired host defense reduces the number of bacteria required to establish an infection. A breach of normal host defenses through surgical intervention (e.g., insertion of a prosthetic device) may enable organisms to cause infection. In addition, the loss of specific immune factors, such as complement activation, tissue-derived inhibitors (e.g., proinflammatory cytokines), cell-mediated response (e.g., T-cell function), and granulocytic or phagocytic function (e.g., neutrophils or macrophages) can greatly increase the risk for SSI development.[19] Vascular occlusive states related to the surgical procedure or those occurring from hypovolemic shock can greatly affect blood flow to the surgical site, thus diminishing host defense mechanisms against microbial invasion. Traumatized

TABLE 132-3 Surgical Site Infection Incidence (%) Stratified by NRC Wound Classification and SENIC Risk Factors[a]

No. of SENIC Risk Factors	Clean	Clean–Contaminated	Contaminated	Dirty
0	1.1	0.6	N/A	N/A
1	3.9	2.8	4.5	6.7
2	8.4	8.4	8.3	10.9
3	15.8	17.7	11.0	18.8
4	N/A	N/A	23.9	27.4

[a]Study on the Efficacy of Nosocomial Infection Control (SENIC) risk factors include abdominal operation, operations lasting >2 hours, contaminated or dirty procedures by National Research Council (NRC) classification, and more than three underlying medical diagnoses.

tissue, hematomas, and the presence of foreign material also lead to more infections. When a foreign body is introduced during a surgical procedure, fewer than 100 bacterial colony-forming units are required to cause an SSI.[20] Studies examining *S. aureus*–contaminated wound infections on the skin of healthy volunteers demonstrate a 10,000-fold reduction in the number of organisms required to establish a wound infection if sutures are not present.[16]

ANTIMICROBIAL RESISTANCE

Colonization of the host with antibiotic-resistant hospital flora prior to or during surgery may lead to an SSI that is unresponsive to routine antibiotic therapy. The most common cause of nosocomially acquired multiresistant organisms is transmission from hospital personnel.[21] Patients treated with broad-spectrum antibiotic therapy are at increased risk for colonization with hospital flora.

With cephalosporins established as first-line agents for prophylaxis over the past decade, organisms resistant to cephalosporins represent the majority of pathogens causing SSIs. The CDC has reported an alarming increase in the incidence of vancomycin-resistant enterococci (VRE) infections, particularly those with *Enterococcus faecium*.[3] Risk factors for VRE colonization include severe concomitant diseases, immunosuppression, admission to the intensive care unit (ICU), previous intraabdominal or cardiothoracic surgery, placement of indwelling catheters, and prolonged courses of antimicrobials, 7 particularly vancomycin.[22,23] In an effort to control the spread of VRE, the CDC has published recommendations that include strict criteria for use of vancomycin as surgical prophylaxis.[23] The guidelines suggest vancomycin substitution for cefazolin as SSI prophylaxis only in cases with a high suspicion of MRSA or in patients with a documented history of a life-threatening allergy to penicillins or cephalosporins. Other limitations to vancomycin use, other than risk of inducing resistant organisms, are the drug's narrow spectrum of activity, its poor penetration into some tissues, and the potential for infusion-related reactions.

The emergence of *S. aureus* displaying intermediate resistance (minimum inhibitory concentration [MIC] ≥8 mcg/mL) further underscores the need to limit routine use of vancomycin for prophylaxis. Methicillin resistance not only limits the options available to treat these infections but is associated with mortality rates twice that of patients with infections caused by methicillin-sensitive *S. aureus* (MSSA).[24] Postoperative factors associated with MRSA include discharge to a long-term care facility and duration of postoperative antibiotic treatment for more than 1 day.[25] Although the use of vancomycin for prophylaxis may be appropriate for some operations performed in hospitals with a high rate of infection due to MRSA, there is little guidance on what constitutes a "high rate" of MRSA infection and whether providing prophylaxis with vancomycin alone will result in fewer SSIs.[26]

Although cefazolin remains a mainstay in cardiovascular SSI prophylaxis, its failure has been reported in cases involving MSSA. In a comparison trial between cefamandole and cefazolin, significantly more failures were attributed to cefazolin, even though the primary pathogen was MSSA.[27] However, a similar trial comparing cefazolin and cefuroxime did not show any difference in SSI incidence between the two regimens.[27] It has been proposed that the β-lactamase expressed by some MSSA is capable of hydrolyzing cefazolin more readily than cefuroxime or cefamandole. Although this trend is disturbing, the overall incidence of cefazolin failure remains low, and cefazolin remains the drug of choice for SSI prophylaxis in cardiovascular surgery.[27]

The increase in frequency of fungal infections in surgical patients has drawn concern. In hospitalized patients, the incidence of nosocomial *Candida* infections nearly doubled from 1992 to 2004.[14,28] Overzealous use of broad-spectrum antibiotics is the most likely cause for this increase. A study of patients undergoing cardiovascular surgery identified sex (female), length of stay in the ICU, and duration of central venous catheterization as risk factors for postoperative *Candida* infections.[29] Although presurgical *Candida* colonization is associated with a higher risk of fungal SSIs, routine preoperative use of prophylactic antifungal agents is not being advocated at this time.[28,30]

SCHEDULING ANTIBIOTIC ADMINISTRATION

3 4 The following principles must be considered when providing antimicrobial surgical prophylaxis: (a) the agents should be delivered to the surgical site prior to the initial incision, and (b) bactericidal antibiotic concentrations should be maintained at the surgical site throughout the surgical procedure. Although animal and human models have demonstrated the efficacy of a single dose of an antibiotic administered just prior to bacterial contamination, long operations often require intraoperative doses of antibiotics to maintain adequate concentrations at the surgical site for the duration of surgery.[31] Antibiotics should be administered with anesthesia just prior to the initial incision. Administration of antibiotics too early may result in concentrations below the MIC toward the end of the operation, and administration too late leaves the patient unprotected at the time of initial incision. In a study examining the timing of antibiotic administration to 2,847 patients receiving prophylaxis, Classen et al[31] evaluated patients who received prophylaxis early (2–24 hours before surgery), preoperative prophylaxis (0–2 hours prior to surgery), perioperative prophylaxis (up to 3 hours after first incision), and postoperative prophylaxis (>3 hours after first incision). The risk of infection was lowest (0.6%) for patients who received preoperative prophylaxis, moderate (1.4%) for those who received perioperative antibiotics, and greatest for those who received postoperative antibiotics (3.3%) or preoperative antibiotics too early (3.8%). The risk for an SSI increases dramatically with each hour from the time of initial incision to the time when antibiotics are eventually administered. For these reasons, prophylactic antibiotics should not be prescribed to be given "on call to the operating room (OR)," which can occur 2 or more hours prior to the initial incision, nor should concurrent therapeutic antibiotics be relied on to provide adequate protection. In both situations, the chance for improperly timed doses is high. Although the landmark study by Classen et al.[31] confirmed that antimicrobial prophylaxis should be administered within 2 hours prior to the initial incision, administration immediately prior to the incision may not allow enough time for the drug to distribute throughout the tissues involved in the surgery.

In a large prospective observational study of 3,836 visceral, trauma, and vascular surgeries where antimicrobial prophylaxis with cefuroxime and metronidazole was employed, the incidence of SSIs was analyzed according to the timing of antimicrobial administration. When antimicrobial prophylaxis was administered within 30 minutes or between 1 and 2 hours before the initial incision, the risk of SSI was greater when compared to antimicrobial prophylaxis administered 30 to 59 minutes prior to the initial incision. The authors conclude that the optimal window for antimicrobial (cefuroxime and metronidazole) is between 30 and 59 minutes prior to the initial incision.[32] This effect may be a function of the pharmacodynamics and pharmacokinetics of the antimicrobial chosen for the prophylactic regimen. A larger study of 4,472 patients undergoing cardiac, orthopedic, and gynecologic surgery with a variety of antimicrobial prophylactic regimens also evaluated the temporal relationship between SSI occurrence and the timing of antibiotics. After excluding patients who received drugs with prolonged

infusion times (i.e., fluoroquinolones and vancomycin), there was a statistically nonsignificant trend toward fewer SSIs in patients who received their prophylactic regimen within the 30 minutes prior to incision as compared with those who received the regimen 31 to 60 minutes prior to incision (odds ratio, OR: 1.74; 95% confidence interval: 0.98–3.04).[33]

Despite the importance of appropriately timed prophylactic antibiotic therapy, few patients receive antibiotics at the optimal time in relation to surgery. Potential barriers include antibiotics ordered after the patient has arrived in the OR, delayed antibiotic preparation or delivery, and use of antibiotics that require long infusion times. One study assessed the timing of prophylactic antibiotics in 100 patients and found that only 26% of patients received an antibiotic dose within 2 hours of the initial surgical incision.[34]

Although most studies comparing single versus multiple doses of prophylactic antibiotics have failed to show a benefit of multidose regimens, the duration of operations in these studies may not be as long as that frequently observed in clinical practice. Proponents of administering a second antibiotic dose during lengthy operations suggest that the risk for SSI is just as great at the end of surgery (during wound closing) as it is during the initial incision. One study of patients undergoing clean-contaminated operations suggests that procedures longer than 3 hours require a second intraoperative dose of cefazolin or substitution of cefazolin with a longer-acting antimicrobial agent.[4] A second study of patients undergoing elective colorectal surgery suggests that low serum antimicrobial concentrations at the time of surgical closure is the strongest predictor of postoperative SSI.[35] Studies of patients undergoing cardiac surgery also have demonstrated a higher infection rate among patients with undetectable antibiotic serum concentrations at the conclusion of the procedure.[36]

One strategy to ensure appropriate redosing of prophylactic antibiotics during long operations is use of a visual or auditory reminder system. One hospital reported its experience with such a system, finding that an automated reminder improved compliance and reduced SSIs. However, even with the reminder system, intraoperative redosing was done in only 68% of eligible patients.[37] Another strategy currently being evaluated is the role of continuous infusions of cefazolin, which one pilot study has found to be a feasible way to ensure adequate serum concentrations of antibiotic during prolonged surgeries.[38] Further trials are required before such an intervention can be recommended.

Underlying disease states that may affect antibiotic metabolism and/or elimination should be considered when developing a prophylactic regimen. For example, patients with thermal burn and spinal cord injuries eliminate certain classes of antibiotics, primarily the aminoglycosides and β-lactams, at unusually high rates compared with controls.[39] Individuals undergoing cardiac bypass may have altered antibiotic disposition related to increased volume of distribution and reduced total body clearance and thus require special dosing consideration.[40]

ANTIMICROBIAL CHOICE

5 The choice of prophylactic antibiotic depends on the type of surgical procedure, the most frequent pathogens seen with this procedure, safety and efficacy profiles of the antimicrobial agent, current literature evidence supporting its use, and cost. Although most SSIs involve the patient's normal flora, antimicrobial selection also must take into account the susceptibility patterns of nosocomial pathogens within each institution. Typically, gram-positive coverage should be included in the choice of surgical prophylaxis because organisms such as *S. aureus* and *S. epidermidis* are encountered commonly as skin flora. The decision to broaden antibiotic prophylaxis to agents with gram-negative and anaerobic spectra of activity depends on both the surgical site (e.g., upper respiratory, gastrointestinal (GI), or genitourinary tract) and whether the operation will transect a hollow viscous or mucous membrane that may contain resident flora.[3]

Although antimicrobial prophylaxis can be administered through a variety of routes (e.g., oral, topical, or intramuscular), the parenteral route is favored because of the reliability by which adequate tissue concentrations may be acheived.[41] Cephalosporins are the most commonly prescribed agents for surgical prophylaxis because of their broad antimicrobial spectrum, favorable pharmacokinetic profile, low incidence of adverse side effects, and low cost. First-generation cephalosporins, such as cefazolin, are the preferred choice for surgical prophylaxis, particularly for clean surgical procedures.[3,4,7] In cases where broader gram-negative and anaerobic coverage is desired, antianaerobic cephalosporins, such as cefoxitin and cefotetan, are appropriate choices. Although third-generation cephalosporins (e.g., ceftriaxone) have been advocated for prophylaxis because of their increased gram-negative coverage and prolonged half-lives, their inferior gram-positive and anaerobic activity and high cost have discouraged the widespread use of these agents.[3,4,7]

Allergic reactions are the most common side effects associated with cephalosporin use. Reactions can range from minor skin manifestations at the site of infusion to rash, pruritus, and rarely anaphylaxis (<0.02%). The structural similarity between penicillins and cephalosporins (each contains a β-lactam ring) has led to considerable confusion about the cross-allergenicity between these two classes of drugs. Twenty percent of the general population is labeled "penicillin allergic," yet of these patients, only 10% to 20% have positive results of a penicillin skin test.[42] The rate of cross-reactivity is ~2%, but as only 20% of all "penicillin-allergic" patients truly are penicillin allergic, the true incidence of cross-reactivity likely is less than 1%. Routine penicillin skin testing is not cost-effective.[42] In summary, the administration of cephalosporins is both safe and cost-effective for many patients who are labeled "penicillin allergic," and they can be used by patients who have not experienced an immediate or type I penicillin allergy.

Vancomycin can be considered for prophylactic therapy in surgical procedures involving implantation of a prosthetic device in which the rate of MRSA is high.[23,43] If the risk of MRSA is low, and a β-lactam hypersensitivity exists, clindamycin can be used for many procedures instead of cefazolin to limit vancomycin use. Infusion-related side effects, such as thrombophlebitis and hypotension, particularly with vancomycin, usually can be controlled by adequate dilution and slower administration rates.[44]

Pseudomembranous colitis secondary to cephalosporins is uncommon and generally easily treated with a short course of oral metronidazole. Although infrequent, bleeding abnormalities related to cephalosporin use have been reported.[45] The primary hematologic effect appears to be inhibition of vitamin K–dependent clotting factors that results in prolongation of the prothrombin time. The mechanism for this effect, most commonly seen with cefotetan, is related to the methylthiotetrazole side chain of the β-lactam molecule. Patients at greatest risk for this hypoprothrombinemic effect have received a prolonged course of these agents and have underlying risk factors for vitamin K deficiency, such as malnutrition.[46]

Because inappropriate prophylactic antibiotic use not only can induce antibiotic resistance but also can negatively affect an institution's antibiotic budget, initiatives to curtail inappropriate antibiotic use have become the focus of many drug use evaluation efforts. Potential sources of inappropriate antibiotic prophylaxis include the use of broad-spectrum antimicrobials when a narrow-spectrum agent is warranted, extending prophylaxis for durations beyond that recommended in published guidelines, and using expensive antibiotics when equivalent, less expensive agents are available. The

most effective tools for ensuring appropriate prophylactic antibiotic prescribing are knowledge of the institutional postoperative infection rate for each type of surgical procedure and familiarity with the bacterial epidemiology patterns for each surgical population. Individualized institutional guidelines that take into account the best literature evidence, institution-based antibiotic susceptibility data, and surgeon preference are important tools for rationalizing antibiotic prophylaxis use.[47]

RECOMMENDATIONS FOR SPECIFIC TYPES OF SURGERY

Guidelines for surgical prophylaxis usually are structured according to the tissues affected during an operation. Although many different surgical procedures may be performed at any one anatomic site, this method of categorization still is optimal because the factors related to the success of a prophylactic regimen, such as the endogenous flora that are expected and the pharmacokinetics, pharmacodynamics, and spectrum of selected antimicrobials, generally are constant for a particular surgical site (see the discussion above). The choice of antimicrobial prophylaxis is always best evaluated using the results of properly conducted clinical trials. In the absence of studies specific to the procedure in question, extrapolation from data on regimens for different procedures in the same anatomic site in question usually can be made. Subsequent modifications to each prophylactic regimen should be based on intraoperative findings or events.

6 A comprehensive review of the surgical prophylaxis literature is beyond the scope of this chapter, but important factors are reviewed here for each type/site of surgery. Specific recommendations are summarized in Table 132–6. The reader is referred to published guidelines and review articles.[3,7,4,41,48]

GI SURGERY

GI surgery can be categorized according to surgical site and infectious risk. Gastroduodenal surgery and hepatobiliary surgery generally are considered to be clean or clean-contaminated surgeries, with SSI rates generally less than 5%. Colorectal surgery, including appendectomies, is considered contaminated because of the large quantities and polymicrobial nature of bacterial flora within the colon. SSI rates for these types of surgeries generally range from 15% to 30%. Emergent abdominal surgery involving bowel perforation or peritonitis is considered a dirty surgical procedure, associated with a greater than 30% risk of SSI, and should be treated with therapeutic rather than prophylactic antibiotics.[3]

Gastroduodenal Surgery

Insignificant numbers of bacteria usually are found in the stomach and duodenum because of their acidity. The rate of SSIs in gastroduodenal surgery generally is low, so procedures in this region can be classified as clean. The risk for an SSI in this population increases with any condition that can lead to bacterial overgrowth, such as obstruction, hemorrhage, or malignancy, or increasing the pH of gastroduodenal secretions with concomitant acid suppression therapy. Antimicrobial prophylaxis is of clinical benefit only in this high-risk population. In most cases, a single dose of intrauenous (IV) cefazolin will provide adequate prophylaxis.[48] For patients with a β-lactam allergy, oral ciprofloxacin is as efficacious as parenteral cefuroxime as prophylactic therapy for gastroduodenal surgery.[49] Antimicrobial prophylaxis is indicated in esophageal surgery only in the presence of obstruction. Postoperative therapeutic antibiotics may be indicated if perforation is detected during surgery, depending on whether an established infection is present.

Use of antibiotic prophylaxis for percutaneous endoscopic gastrostomy placement is controversial.[50] Although postoperative peristomal infection can occur in up to 30% of patients, clinical trials with cefazolin given 30 minutes preoperatively in this population are conflicting.[50] A pharmacoeconomic study that incorporated a meta-analysis of available studies to determine efficacy suggested that antibiotic prophylaxis was cost-effective for patients undergoing percutaneous endoscopic gastrostomy placements.[51]

Hepatobiliary Surgery

Although bile normally is sterile, and the SSI rate after biliary surgery is low, antibiotic prophylaxis is of benefit in this population. Bile contamination (bactobilia) can increase the frequency of SSIs and is present in many patients (e.g., those with acute cholecystitis or biliary obstruction and those of advanced age).[48] In general, however, the correlation between bactobilia in surgical specimens and the subsequent pathogens implicated in an SSI is poor. The most frequently encountered organisms are *E. coli, Klebsiella* species, and enterococci. *Pseudomonas* is an uncommon finding in the absence of cholangitis. Trials comparing first-, second-, and third-generation cephalosporins have not demonstrated benefit over single-dose cefazolin prophylaxis even in high-risk patients (e.g., age >60 years, previous biliary surgery, acute cholecystitis, jaundice, obesity, diabetes, and common bile duct stones).[52] Ciprofloxacin and levofloxacin are effective alternatives for β-lactam-allergic patients undergoing open cholecystectomy.[53,54] In fact, orally administered levofloxacin appears to provide similar intraoperative gallbladder tissue concentrations.[54] For low-risk patients undergoing elective laparoscopic cholecystectomy, antibiotic prophylaxis is not of benefit and is not recommended.[55] The risk for SSIs in cirrhotic patients undergoing transjugular intrahepatic portosystemic shunt surgery may be reduced with a single prophylactic dose of ceftriaxone[56] but not with single doses of shorter-acting cephalosporins.[57]

Although surgeons may use presumptive antibiotic therapy for patients with acute cholecystitis or cholangitis and defer surgery until the patient is afebrile in an effort to decrease the risk of subsequent infections, this practice is controversial. Detection of an active infection during surgery (e.g., gangrenous gallbladder and suppurative cholangitis) is an indication for a course of postoperative therapeutic antibiotics. In either case, antibiotics with additional antianaerobic activity (e.g., cefoxitin or cefotetan) are indicated.[58]

Appendectomy

Suspected appendicitis is a frequent cause of abdominal surgery. Numerous antibiotic regimens, all with activity against gram-positive and gram-negative aerobes and anaerobic pathogens, are effective in reducing SSI incidence.[48] A cephalosporin with antianaerobic activity, such as cefoxitin or cefotetan, is recommended as first-line therapy; however, a comparative trial of cefoxitin and cefotetan suggests that cefotetan may be superior, possibly because of its longer duration of action.[59] In patients with β-lactam allergy, metronidazole in combination with gentamicin is an effective regimen. Broad-spectrum antibiotics covering nosocomial pathogens (e.g., *Pseudomonas*) do not further reduce SSI risk and instead may increase the cost of therapy and promote bacterial resistance.[60] Although single-dose therapy with cefotetan is adequate, prophylaxis with cefoxitin may require intraoperative dosing if the procedure extends beyond 3 hours. Established intraabdominal infections (e.g., gangrenous or perforated appendix) require an appropriate course of postoperative therapeutic antibiotics. Laparoscopic appendectomy produces lower postoperative infection rates than open appendectomy; however, antimicrobial prophylaxis was used for all patients in these studies; thus, the role for prophylaxis in this population remains poorly studied.[61]

TABLE 132-6 Most Likely Pathogens and Specific Recommendations for Surgical Prophylaxis

Type of Operation	Likely Pathogens	Recommended Prophylaxis Regimen[a]	Comments	Grade of Recommendation[b]
GI surgery				
Gastroduodenal	Enteric gram-negative bacilli, gram-positive cocci, oral anaerobes	Cefazolin 1 g × 1 (see text for recommendations for percutaneous endoscopic gastrostomy)	High-risk patients only (obstruction, hemorrhage, malignancy, acid suppression therapy, morbid obesity)	IA
Cholecystectomy	Enteric gram-negative bacilli, anaerobes	Cefazolin 1 g × 1 for high-risk patients Laparoscopic: none	High-risk patients only (acute cholecystitis, common duct stones, previous biliary surgery, jaundice, age >60 years, obesity, diabetes mellitus)	IA
Transjugular intrahepatic portosystemic shunt (TIPS)	Enteric gram-negative bacilli, anaerobes	Ceftriaxone 1 g × 1	Longer-acting cephalosporins preferred	IA
Appendectomy	Enteric gram-negative bacilli, anaerobes	Cefoxitin or cefotetan 1 g × 1	Second intraoperative dose of cefoxitin may be required if procedure lasts longer than 3 hours	IA
Colorectal	Enteric gram-negative bacilli, anaerobes	Orally: neomycin 1 g + erythromycin base 1 at 1 PM, 2 PM, and 11 PM 1 day preoperatively plus mechanical bowel preparation IV: cefoxitin or cefotetan 1 g × 1	Benefits of oral plus IV is controversial except for colostomy reversal and rectal resection	IA
GI endoscopy	Variable, depending on procedure, but typically enteric gram-negative bacilli, gram-positive cocci, oral anaerobes	Orally: amoxicillin 2 g × 1 IV: ampicillin 2 g × 1 or cefazolin 1 g × 1	Recommended only for high-risk patients undergoing high-risk procedures (see text)	IA
Urologic surgery				
Prostate resection, shock-wave lithotripsy, ureteroscopy	*Escherichia coli*	Ciprofloxacin 500 mg orally or trimethoprim-sulfamethoxazole 1 DS tablet	All patients with positive pre-operative urine cultures should receive a course of antibiotic treatment	IA–IB
removal of external urinary catheters, cystography, urodynamic studies, simple cystourethroscopy	*E. coli*	Ciprofloxacin 500 mg orally or trimethoprim-sulfamethoxazole 1 DS tablet	Should be considered only in patients with risk factors (see text)	IB
Gynecological surgery				
Cesarean section	Enteric gram-negative bacilli, anaerobes, group B streptococci, enterococci	Cefazolin 2 g × 1	Can be given before initial incision or after cord is clamped	IA
Hysterectomy	Enteric gram-negative bacilli, anaerobes, group B streptococci, enterococci	Vaginal: cefazolin 1 g × 1 Abdominal: cefotetan 1 g × 1 or cefazolin 1 g × 1	Metronidazole 1 g IV × 1 is recommended alternative for penicillin allergy	IA
Head and neck surgery				
Maxillofacial surgery	*Staphylococcus aureus*, streptococci oral anaerobes	Cefazolin 2 g or clindamycin 600 mg	Repeat intraoperative dose for operations longer than 4 hours	IA
Head and neck cancer resection	*S. aureus*, streptococci oral anaerobes	Clindamycin 600 mg at induction and every 8 hours × 2 more doses	Add gentamicin for clean–contaminated procedures	IA
Cardiothoracic surgery				
Cardiac surgery	*S. aureus, Staphylococcus epidermidis, Corynebacterium*	Cefazolin 1 g every 8 hours × 48 h	Patients >80 kg (176 lb) should receive 2 g of cefazolin instead; in areas with high prevalence of *S. aureus* resistance, vancomycin should be considered	IA
Thoracic surgery	*S. aureus, S. epidermidis, Corynebacterium,* enteric gram-negative bacilli	Cefuroxime 750 mg IV every 8 hours × 48 hours	First-generation cephalosporins are deemed inadequate, and shorter durations of prophylaxis have not been adequately studied	IA
Vascular surgery				
Abdominal aorta and lower extremity vascular surgery	*S. aureus, S. epidermidis,* enteric gram-negative bacilli	Cefazolin 1 g at induction and every 8 hours × 2 more doses	Although complications from infections may be infrequent, graft infections are associated with significant morbidity	IB
Orthopedic surgery				
Joint replacement	*S. aureus, S. epidermidis*	Cefazolin 1 g × 1 preoperatively, then every 8 hours × 2 more doses	Vancomycin reserved for penicillin-allergic patients or where institutional prevalence of methicillin- resistant *S. aureus* warrants use	IA

(continued)

TABLE 132-6 Most Likely Pathogens and Specific Recommendations for Surgical Prophylaxis (continued)

Type of Operation	Likely Pathogens	Recommended Prophylaxis Regimen[a]	Comments	Grade of Recommendation[b]
Hip fracture repair	*S. aureus, S. epidermidis*	Cefazolin 1 g × 1 preoperatively, then every 8 hours for 48 hours	Compound fractures are treated as if infection is presumed	IA
Open/compound fractures	*S. aureus, S. epidermidis,* gram-negative bacilli, polymicrobial	Cefazolin 1 g × 1 preoperatively, then every 8 hours for a course of presumed infection	Gram-negative coverage (i.e., gentamicin) often indicated for severe open fractures	IA
Neurosurgery				
CSF shunt procedures	*S. aureus, S. epidermidis*	Cefazolin 1 g every 8 h × 3 doses or ceftriaxone 2 g × 1	No agents have been shown to be better than cefazolin in randomized comparative trials.	IA
Spinal surgery	*S. aureus, S. epidermidis*	Cefazolin 1 g × 1	Limited number of clinical trials comparing different treatment regimens	IB
CSF shunt procedures	*S. aureus, S. epidermidis*	Cefazolin 1 g every 8 h × 3 doses or ceftriaxone 2 g × 1	No agents have been shown to be better than cefazolin in randomized comparative trials.	IA
Craniotomy	*S. aureus, S. epidermidis*	Cefazolin 1 g × 1 or cefotaxime 1 g × 1	IV × 1 can be substituted for patients with penicillin allergy Trimethoprim-sulfamethoxazole (160/800 mg)	IA

[a]One-time doses are optimally infused at induction of anesthesia except as noted. Repeat doses may be required for long procedures. See text for references.
[b]Strength of recommendations:
Category IA: Strongly recommended and supported by well-designed experimental, clinical, or epidemiologic studies.
Category IB: Strongly recommended and supported by some experimental, clinical, or epidemiologic studies and strong theoretical rationale.
Category II: Suggested and supported by suggestive clinical or epidemiologic studies or theoretical rationale.
CSF = cerebrospinal fluid, DS = double strength, GI = gastrointestinal, IV = intravenous(ly).

Colorectal Surgery

In the absence of adequate prophylactic therapy, the risk for SSI after colorectal surgery is high because of the significant bacterial counts in fecal material present in the colon (frequently $>10^9$ per gram). Anaerobes and gram-negative aerobes predominate, but gram-positive aerobes also may play an important role. Reducing this bacterial load with a thorough bowel preparation regimen (4 L of polyethylene glycol solution or 90 mL of sodium phosphate solution administered orally the day before surgery) is controversial; however, 99% of surgeons in a survey routinely use mechanical preparation.[62] Risk factors for SSIs include age over 60 years, hypoalbuminemia, poor preoperative bowel preparation, corticosteroid therapy, malignancy, and operations lasting longer than 3.5 hours.[7]

Antimicrobial prophylaxis reduced mortality from 11.2% to 4.5% in a pooled analysis of trials comparing antimicrobial prophylaxis with no prophylaxis for colon surgery.[65] Effective antibiotic prophylaxis reduces even further the risk for an SSI. Several oral regimens designed to reduce bacterial counts in the colon have been studied.[48] The combination of 1 g neomycin and 1 g erythromycin base given orally 19, 18, and 9 hours preoperatively is the regimen most commonly used in the United States.[66] Neomycin is poorly absorbed but provides intraluminal concentrations that are high enough to effectively kill most gram-negative aerobes. Oral erythromycin is only partially absorbed but still produces concentrations in the colon that are sufficient to suppress common anaerobes. If surgery is postponed, the antibiotics must be readministered to maintain efficacy. Optimally, the bowel preparation regimen should be completed prior to starting the oral antibiotic regimen. This is of particular concern because most procedures now are performed electively on a "same-day surgery" basis. In this case, the bowel preparation regimen is self-administered by the patient at home on the day prior to hospital admission, and compliance cannot be monitored carefully.

Patients who cannot take oral medications should receive parenteral antibiotics. Cefoxitin or cefotetan is used most commonly, but other second- and some third-generation cephalosporins also are effective.[67] The role of metronidazole in combination with cephalosporin therapy is unclear. Only retrospective evidence suggests that the addition of metronidazole to a cephalosporin or extended-spectrum penicillin provides additional benefit.[68] Until this finding is confirmed in prospective studies, metronidazole should be reserved for combination therapy with cephalosporins with poor anaerobic coverage (e.g., cefazolin). At this time, the evidence recommending the addition of metronidazole to cephalosporins with anaerobic activity (e.g., cefotaxime, cefoxitin, and ceftriaxone) is insufficient.[69] For β-lactam-allergic patients, perioperative doses of gentamicin and metronidazole have been used. Combination therapy (i.e., oral and IV therapy) is controversial. A Cochrane review suggests that combination therapy is superior to either oral or IV antibiotics alone.[69] However, the largest study (491 patients) comparing combination therapy with only IV therapy, which showed no benefit with combination therapy, was not included in the meta-analysis.[70] Postoperative antibiotics generally are unnecessary in the absence of any untoward events or findings during surgery. IV antibiotics are required for colostomy reversal and rectal resection because enterally administered antibiotics will not reach the distal segment that is to be reanastomosed or resected.[71]

CLINICAL CONTROVERSY

A randomized trial of 380 patients undergoing elective colorectal surgery suggests that SSIs are not reduced by preoperative mechanical bowel preparation.[63] This finding was confirmed in a meta-analysis showing that mechanical bowel preparation does not reduce the risk of anastomotic leakage or other complications, including postoperative infection.[64] Despite this new evidence, mechanical bowel preparations continue to be a standard of practice prior to elective bowel surgery.

Gastrointestinal Endoscopy

Despite the large number of endoscopic procedures performed each year, the rate of postprocedural infection is relatively low. The highest bacteremia rates have been reported in patients undergoing esophageal dilation for stricture or sclerotherapy for management of esophageal varices. Although postprocedural bacteremia can occur in as many as 22% of patients, the bacteremia usually is transient (<30 minutes) and rarely results in clinically significant infection. Therefore, antimicrobial prophylaxis is routinely recommended only for high-risk patients (e.g., patients with prosthetic heart valves, a history of endocarditis, systemic-pulmonary shunt, synthetic vascular graft <1 year old, complex cyanotic congenital heart disease, obstructed bile duct, or liver cirrhosis, as well as immunocompromised patients) undergoing high-risk procedures (e.g., stricture dilation, variceal sclerotherapy, and endoscopic retrograde cholangiopancreatography).[72] Single-dose preprocedural regimens similar to those for endocarditis prophylaxis are most common (amoxicillin for patients who can tolerate oral premedication or either IV ampicillin or cefazolin). A meta-analysis of antimicrobial prophylaxis for endoscopic placement of percutaneous feeding tubes also suggests that a single preoperative dose of antibiotics reduces the risk of postoperative infection compared with no antibiotic (6.4% vs 24%).[73] Consensus guidelines have adopted this recommendation and suggest a single dose of cefazolin within 30 minutes prior to the procedure.[72]

UROLOGIC SURGERY

Preoperative bacteriuria is the most important risk factor for development of an SSI after urologic surgery. All patients should have a preoperative urinalysis and should receive therapeutic antibiotics if bacteriuria is detected. Patients with sterile urine preoperatively are at low risk for developing an SSI, and the benefit of prophylactic antibiotics in this setting is controversial. Antibiotic prophylaxis is recommended for all patients undergoing transurethral resection of the prostate or bladders tumors, shock-wave lithotripsy, percutaneous renal surgery, or ureteroscopy.[74] The exact incidence of SSIs in this population is obscured by the frequent use of postoperative urinary catheters and the subsequent risk of bacteriuria. *E. coli* is the most frequently encountered organism. Routine use of broad-spectrum antibiotics, such as third-generation cephalosporins and fluoroquinolones, does not decrease SSI rates more than cefazolin, but the ability to administer fluoroquinolones orally rather than intravenously makes antimicrobial prophylaxis with ciprofloxacin easier and less expensive.[75] First- or second-generation cephalosporins are considered the antimicrobial agents of choice for patients undergoing open or laparoscopic procedures involving entry into the urinary tract and any urologic surgical procedures involving the intestine, rectum, vagina, or implanted prosthesis.[74] The evidence for antimicrobial prophylaxis for the removal of external urinary catheters, cystography, urodynamic studies, simple cystourethroscopy, and open or laparoscopic urologic procedures that do not involve entry into the urinary tract is not as evident. Only patients considered to have risk factors (patients of advanced age; those with anatomic anomalies, poor nutritional history, externalized catheters, colonized endogenous/exogenous material, or distant coexistent infection; smokers; immunocompromised patients; and those who are hospitalized for a prolonged stay) should receive antimicrobial prophylaxis.[74]

OBSTETRIC AND GYNECOLOGIC SURGERIES

Cesarean Section

Cesarean section is the most frequently performed surgical procedure in the United States.[7] Prophylactic antibiotics are given to prevent endometritis, the most commonly occurring SSI. In the past, antibiotics were recommended for only high-risk patients, including those with premature membrane rupture or those not receiving prenatal care. Several large trials, as well as a meta-analysis of 81 trials, have shown benefit in administering prophylactic antibiotics to all women undergoing emergent or elective cesarean section regardless of their underlying risk factors.[76] Cefazolin remains the drug of choice despite the wide spectrum of potential pathogens, and a single 2 g dose appears to be superior to single or multiple 1 g doses.[77] Providing a broader spectrum of coverage with cefoxitin (for anaerobes) or piperacillin (for *Pseudomonas* or enterococci) does not further reduce postoperative infection rates. For patients with a β-lactam allergy, preoperative metronidazole is an acceptable alternative.[76]

CLINICAL CONTROVERSY

During a cesarean section, unlike other surgical procedures, the most appropriate timing of antibiotic administration is controversial. Traditionally, antimicrobials were administered after the initial incision and when the umbilical cord was clamped in an attempt to minimize infant drug exposure, which theoretically could mask the signs of neonatal sepsis and select resistant organisms in infants who develop infections. Recent studies and systematic reviews, however, suggest that preincision antibiotics are more effective at preventing postoperative endometritis and other SSIs but are underpowered to evaluate the impact on neonatal infectious complications.[78]

Hysterectomy

The most important factor affecting the incidence of SSI after hysterectomy is the type of procedure performed. Vaginal hysterectomies are associated with a high rate of postoperative infection when performed without the benefit of prophylactic antibiotics because of the polymicrobial flora normally present at the operative site.[79] As with cesarean sections, cefazolin is the drug of choice for vaginal hysterectomies despite the wide spectrum of possible pathogens.[79] The American College of Obstetricians and Gynecologists (ACOG) recommends a single dose of either cefazolin or cefoxitin.[80] For patients with a β-lactam allergy, a single preoperative dose of either metronidazole or doxycycline also is effective.[80]

Prophylactic antibiotics are recommended for abdominal hysterectomy despite the lack of bacterial contamination from the vaginal flora. Both cefazolin and antianaerobic cephalosporins (e.g., cefoxitin and cefotetan) have been studied extensively. Single-dose cefotetan is superior to single-dose cefazolin,[81] and the investigators suggest that cefotetan should be the drug of choice for abdominal hysterectomies. However, other investigators suggest that either agent is appropriate, provided 24 hours of antimicrobial coverage is not exceeded.[7] The ACOG guidelines suggest that first-, second-, or third-generation cephalosporins can be used for prophylaxis.[80] Metronidazole also is effective and can be used if patients are allergic to β-lactam antibiotics.[79] Antibiotic prophylaxis may not be required in laparoscopic gynecologic surgery or tubal microsurgery.[82] As with other surgical procedures, perioperative events and findings may require the use of therapeutic antibiotics after surgery.

HEAD AND NECK SURGERY

The use of prophylactic antibiotics during head and neck surgery depends on the procedure type. Clean procedures (per NRC definition), such as parotidectomy and simple tooth extraction, are associated with a low incidence of SSI. Head and neck procedures involving an incision through a mucosal layer are associated with a higher risk for SSI. The normal flora of the mouth is polymicrobial; both

anaerobes and gram-positive aerobes predominate. Although typical doses of cefazolin usually are ineffective for anaerobic infections, a 2 g dose produces concentrations high enough to inhibit these organisms. A pharmacokinetic study suggested that a single dose of clindamycin is adequate for prophylaxis in maxillofacial surgery unless the procedure lasts longer than 4 hours, when a second dose should be administered intraoperatively.[83] For most head and neck cancer resection surgeries, including free-flap reconstruction, 24 hours of clindamycin is appropriate, and no additional benefit of extending therapy beyond 24 hours is seen. A combination of clindamycin and gentamicin to cover aerobic, anaerobic, and gram-negative bacteria in clean-contaminated oncologic surgery is recommended.[84] Topical therapy with clindamycin, amoxicillin–clavulanate, and ticarcillin–clavulanate has been described in small trials, but the exact role of topical antibiotics is not defined.[85] Antimicrobial prophylaxis is not indicated for endoscopic sinus surgery without nasal packing.[41]

CARDIOTHORACIC SURGERY

Although cardiac surgery generally is considered a clean procedure, antibiotic prophylaxis lowers SSI incidence.[48] The substantial morbidity related to an SSI in this population, coupled with the routine implementation of prosthetic devices, further justifies the routine use of prophylaxis.[86] Patients who develop SSIs after coronary artery bypass graft surgery have a mortality rate of 22% at 1 year compared with 0.6% for those who do not develop an SSI.[87] Risk factors for developing an SSI after cardiac surgery include obesity, renal insufficiency, connective tissue disease, reexploration for bleeding, and poorly timed administration of antibiotics.[86] Skin flora pathogens predominate; gram-negative organisms are rare.

Cefazolin has been studied extensively and is considered the drug of choice. Although several studies and a meta-analysis advocate the use of second-generation cephalosporins (e.g., cefuroxime) rather than cefazolin, various methodologic flaws in these studies have limited the extrapolation of these results to practice. Cefazolin was as effective as cefuroxime in a large randomized trial of 702 patients undergoing open heart surgery and thus remains the standard of care.[88] Both patient weight and timing of cefazolin administration relative to surgery must be considered when developing a dosing strategy. Patients weighing >80 kg (176 lb) should receive 2 g cefazolin rather than 1 g. Doses should be administered no earlier than 60 minutes before the first incision and no later than the beginning of induction.[84] Extending therapy beyond 48 hours does not further reduce SSI rates. Single-dose cefazolin therapy may be sufficient but is not recommended by the Society of Thoracic Surgeons at this time pending further study.[89]

Routine vancomycin administration may be justified in hospitals having a high incidence of MRSA or when sternal wounds are to be explored surgically for possible mediastinitis. However, a large comparative trial enrolling almost 900 patients in a single center with a high prevalence of MRSA infections found that both cefazolin and vancomycin had similar efficacy in preventing SSI in patients undergoing cardiac surgery that required sternotomy.[90] Mediastinitis constitutes a failure of a prior prophylactic regimen. Continued postoperative vancomycin should be guided by culture and sensitivity data.[42] Subsequent antibiotic therapy is guided by intraoperative findings.

Pulmonary resection is associated with significant SSI risk, and prophylactic antibiotics have an established role in preventing postoperative infectious morbidity. Pleuropulmonary infections are much more common than wound infections, and pathogenic organisms likely migrate from the oral cavity or pharynx.[91] First-generation cephalosporins are inadequate; 48 hours of cefuroxime is preferred. A regimen of ampicillin–sulbactam is superior to first-generation cephalosporins, but further studies are required before this agent can be recommended as first-line prophylactic therapy.[92]

VASCULAR SURGERY

Vascular surgery, like cardiac surgery, generally is considered clean by NRC criteria. Although vascular graft infections occur infrequently (3%–5%), the associated morbidity and mortality are extensive because treatment often requires surgical graft removal along with therapeutic antibiotic therapy.[93] Prophylactic antibiotics are of benefit, particularly for procedures involving the abdominal aorta and the lower extremities. Cefazolin is regarded as the drug of choice.[94] Twenty-four hours of prophylaxis with cefazolin is adequate; longer courses may lead to bacterial resistance.[95] For patients with β-lactam allergy, 24 hours of oral ciprofloxacin has been shown to be effective.[93]

ORTHOPEDIC SURGERY

Most orthopedic surgery is clean by definition; thus, prophylactic antibiotics generally are indicated only when prosthetic materials (e.g., pins, plates, and artificial joints) are implanted.[20] A late-occurring infectious complication in this surgical population can result in substantial morbidity and may lead to prosthesis failure and subsequent removal. Staphylococci are the most frequently encountered pathogens; gram-negative aerobes are infrequent. The use of cefazolin is supported by substantial evidence in the literature and therefore is the prophylactic agent of choice. Vancomycin, although effective, is not recommended for routine use unless a patient has a documented history of a serious allergy to β-lactams, or the propensity for MRSA infections at a particular institution necessitates its use. The current recommended duration of prophylaxis for joint replacement and hip fracture surgery is 24 hours.[7] Antibiotic-impregnated cement and beads have been used to lower SSI rates, but conclusive data regarding their efficacy are lacking.[20]

Patients suffering open (compound) fractures are particularly susceptible to infection because bacterial contamination almost always has occurred already. Under these circumstances, the use of antibiotics is presumptive. In this setting, cefazolin often is combined with an aminoglycoside, but controlled trials are lacking.[96] A clinical trial comparing clindamycin and cloxacillin suggests that clindamycin is superior and may be appropriate as monotherapy for Gustilo type I and II open fractures but not for type III fractures, for which added gram-negative activity is recommended.[97] Duration of antibiotic therapy is highly variable and depends on surgical findings during debridement, results of intraoperative cultures, and clinical status. A prospective trial comparing short (<24 hours) and long (>24 hours) courses of antimicrobial prophylaxis for severe trauma suggests that longer courses of antibiotics do not offer additional benefit and may be associated with the development of resistant infections.[98] However, established joint infections and osteomyelitis require an extended course of therapeutic antibiotics.

NEUROSURGERY

Definitive recommendations on the role of antibiotic prophylaxis in neurosurgery cannot be made at this time.[99] Although the rates of SSI after these generally clean operations are low, the morbidity and mortality of SSI, should they occur, are high. Procedures involving cerebrospinal fluid (CSF) shunt placement should be considered separately because this procedure involves placement of a foreign body and is associated with higher infection rates. When choosing an antibiotic, considerations include not only the spectrum of activity but also the penetration of the agent into the site of action (CSF). A meta-analysis suggested that single doses of cefazolin or, where required, vancomycin appear to lower SSI risk after craniotomy.[100] The largest prospective randomized trial to date of 826 patients undergoing clean neurosurgical procedures suggested that a single dose of ceftizoxime

was as effective as a combination regimen of single-dose vancomycin and gentamicin. The authors also reported that ceftizoxime was better tolerated and more consistently achieved adequate CSF levels to inhibit the most common organisms.[101] A study of 780 patients undergoing neurosurgical procedures that included shunt surgery reported that single doses of cefotaxime and trimethoprim–sulfamethoxazole were equally effective in preventing SSIs.[102] Most studies of procedures involving a shunt have been small in size and do not consistently show lower infection rates with antibiotic prophylaxis, although the results of a systematic review and meta-analysis suggest that a significant improvement in the incidence of shunt infection with 24 hours of systemic antibiotics (i.e., cefazolin) and the use of antibiotic-impregnated catheters independently.[103]

SSIs associated with spinal surgery are rare but devastating when they occur. The use of antimicrobial prophylaxis in this setting is warranted and recommended by a meta-analysis.[104] Large randomized, controlled trials are lacking, but cefazolin is the antibiotic recommended most commonly. Cephalosporin penetration into the vertebral disk has been questioned. Some small studies suggest that the addition of gentamicin, which has better penetration, might be warranted; however, there is a paucity of clinical trials comparing these two regimens.[105]

MINIMALLY INVASIVE AND LAPAROSCOPIC SURGERY

Laparoscopic surgeries are being performed more frequently for a variety of different operations, including gynecologic, orthopedic, and biliary surgeries. This minimally invasive technique is associated with smaller wounds, fewer infectious complications, smaller inflammatory response, and therefore a better-preserved immune response to infection compared with the open surgical approach.[106] The role of antimicrobial prophylaxis in this setting depends on the type of surgery performed and preexisting risk factors for infection. Unfortunately, few large prospective, placebo-controlled trials have determined in which patients and surgeries antimicrobial prophylaxis is warranted.

In addition to the recommendations for previously mentioned laparoscopic procedures, there is a variety of levels of evidence for prophylaxis in other laparoscopic and endoscopic procedures. Patients undergoing endoscopic retrograde cholangiopancreatography do not need antimicrobial prophylaxis unless biliary obstruction is evident. In these situations, a single 1 g dose of cefazolin will suffice.[107] The role of antimicrobial prophylaxis for transurethral resection of the prostate is better established. A third-generation cephalosporin such as ceftriaxone (or cotrimoxazole for severely β-lactam-allergic patients) can be recommended as single-dose prophylaxis, especially for patients with nonsterile urine preoperatively or indwelling catheters.[107] Insertion of peritoneal dialysis catheters by laparoscopic technique is associated with significantly lower rates of postoperative infection. With SSI rates less than 5%, prophylactic antimicrobial therapy may not be warranted, but this has not been studied in a sufficiently large placebo-controlled trial. If the decision to provide antimicrobial prophylaxis is made, a single dose of cefazolin will suffice.[107]

NONPHARMACOLOGIC INTERVENTIONS

Strategies other than antimicrobial and aseptic technique for reducing postoperative infections have been investigated in different types of surgeries. The most commonly cited and practiced interventions include intraoperative maintenance of normothermia, provision of supplemental oxygen in the perioperative period, and aggressive perioperative glucose control.

CLINICAL CONTROVERSY

Several studies have investigated the role of specialized enteral formulas fortified with a variety of immunomodulating micronutrients thought to enhance the immune response and gut function after trauma or surgery. Although many clinicians are exploring the role of supplements such as glutamine, arginine, omega fatty acids, and nucleotides, no study to date has shown a significant reduction in postoperative infection rates using these formulations.

CLINICAL CONTROVERSY

Although interventions to maintain normothermia intraoperatively, provide supplemental oxygen in the perioperative period, and aggressively control perioperative glucose show a significant reduction in SSI, they cannot be generalized to all types of surgeries. However, given the simplicity and low cost of these interventions, many clinicians consider applying these measures outside of the studied population(s). At this time, pending further research, these interventions can be recommended for routine use only in the type of patient or surgery for which they were studied.

Core body temperature can fall by 1°C to 1.5°C (33.8–34.7°F) intraoperatively in patients under general anesthesia. Intraoperative hypothermia has been associated with impaired immune function, decreased blood flow to the surgical site, decreased tissue oxygen tension, and an increased risk of SSI. Efforts to maintain intraoperative normothermia should be exercised and may include the use of warming blankets and IV fluid warmers to maintain core body temperature above 36°C (97°F). One prospective trial of 200 patients undergoing colorectal surgery found that maintenance of normothermia reduced postoperative infection rates along with other morbidity parameters, including length of stay.[108]

Low oxygen tension in the tissues that make up the surgical site increases the risk of bacterial colonization and subsequent SSI by decreasing the efficiency of neutrophil activity. Administration of high concentrations of oxygen (80% via ventilator or 12 L/min via a nonrebreather mask) reduced postoperative infection rates significantly in a multicenter randomized trial of 500 patients undergoing colorectal surgery.[109]

Diabetes and poor glucose control are well-known risk factors for SSI. The increased risk of infection is thought to be due to both macrovascular (vasculopathy and venoocclusive disease) and microvascular (subtle immunologic deficiencies, including neutrophil dysfunction and reduced complement and antibody activity) complications. Aggressive control of perioperative blood glucose level decreases the incidence of SSI in diabetics undergoing cardiac surgery and is being evaluated in other types of surgery and in nondiabetic patients.[110]

QUALITY ASSURANCE AND PHARMACOECONOMIC IMPLICATIONS

The recommendations and literature reviewed in this chapter indicate that SSIs are preventable with appropriately chosen and timed prophylactic therapy in combination with meticulous aseptic technique and a variety of nonantimicrobial methods. Despite this practice, infection is the most common complication seen postoperatively. For this reason, many organizations, including

the Centers for Medicare and Medicaid Service (CMS), CDC, and Joint Commission on Accreditation of Healthcare Organizations (JCAHO), have mandated a formalized approach to improving patient safety and reducing SSIs. Quality assurance data collected from Medicare inpatients found that two of the three performance measures of the National Surgical Infection Project (SIP), implemented by the CMS and the CDC in 2002, are not consistently being met.[111] Although 92.6% of patients were given a prophylactic antimicrobial regimen consistent with published guidelines, only 55.7% of these surgical patients had parenteral antimicrobial prophylaxis initiated within 1 hour prior to incision, and the prophylactic antimicrobial was discontinued within 24 hours after surgery end time in only 40.7% of patients.[111] Strategies have been investigated and shown to improve surgical antibiotic prophylaxis practices for these three outcomes as part of the SIP. These three performance outcomes have been adopted as core measures by the JCAHO as publicly reported quality measure by the Hospital Quality Alliance. However, in light of a lack of clear guidance on what constitutes "high rates" of MRSA in published SIP guidelines, the national shortage of antibiotics recommended for patients undergoing general abdominal colorectal surgery (e.g., cefotetan, cefoxitin), and conflicting recommendations for prevention of endocarditis in patients undergoing surgery who have coexisting valvular heart disease, the CMS and the JCAHO have temporarily suspended the public reporting of these SIP quality measures.[112] Standardized institutional guidelines can effectively ensure appropriate prophylactic antimicrobial therapy and ultimately reduce SSIs at individual institutions. Strategies for improving such programs are outlined in Table 132–7.[113]

It is paramount to consider the cost implications of pharmacotherapy guidelines that affect a large number of patients. Although investigators have incorporated basic financial analysis into the results of antibiotic prophylaxis comparative trials,[42,47,50,87] robust pharmacoeconomic studies of various regimens of antimicrobial prophylaxis in surgery are lacking. Most of these are cost minimization studies because only drug acquisition costs are considered. Studies that incorporate all relevant drug and treatment costs in relation to pertinent patient outcomes, such as incidence of SSIs, hospital length of stay, and antibiotic-related adverse events, are needed.

TABLE 132-7 Strategies for Implementing an Institutional Program to Ensure Appropriate use of Antimicrobial Prophylaxis in Surgery

1. Educate
Develop an educational program that enforces the importance and rationale of timely antimicrobial prophylaxis.
Make this educational program available to all healthcare practitioners involved in the patient's care.
2. Standardize the ordering process
Establish a protocol (e.g., a preprinted order sheet) that standardizes antibiotic choice according to current published evidence, formulary availability, institutional resistance patterns, and cost.
3. Standardize the delivery and administration process
Use system that ensures antibiotics are prepared and delivered to the holding area in a timely fashion.
Standardize the administration time to less than 1 hour preoperatively.
Designate responsibility and accountability for antibiotic administration.
Provide visible reminders to prescribe/administer prophylactic antibiotics (e.g., checklists).
Develop a system to remind surgeons/nurses to readminister antibiotics intraoperatively during long procedures.
4. Provide feedback
Follow up with regular reports of compliance and infection rates.

EVALUATION OF THERAPEUTIC OUTCOMES

When evaluating the outcome of surgical antibiotic prophylaxis, it is important to differentiate any potential SSI from other postoperative infection or complication. Although fever and leukocytosis are common in the immediate postoperative period, they typically resolve with prompt ambulation, timely removal of invasive devices, prevention and/or resolution of atelectasis through optimal respiratory care, and effective analgesia. It is important to remember that the emergence of distal infections, such as pneumonia, does not constitute a failure of surgical prophylaxis. Prophylaxis should be as short as possible because prolonged prophylactic regimens may contribute to the selection of resistant organisms and may make any infection more difficult to treat.

Surgical site appearance is the most important determinant of the presence of an infection. Drainage of pus from the incision accompanied by redness, warmth, and pain or tenderness is highly suggestive of an SSI. By definition, any surgical site that requires incision and drainage by the surgeon is considered infected regardless of appearance. Failure to heal and wound dehiscence also are seen with SSIs, although surgical technique and nutritional status may be important contributing factors.

The presentation of signs and symptoms consistent with an SSI in relation to previous surgery is an important consideration when evaluating therapeutic outcomes after surgical prophylaxis. Many SSIs will not be evident during acute hospitalization. In fact, SSIs may not become evident until up to 30 days later or, in the case of prosthesis implantation, up to 1 year later. Thus, the true incidence of SSI can be determined only by completing comprehensive postdischarge surveillance. All studies investigating the efficacy of surgical prophylaxis must include adequate postdischarge follow-up to be able to thoroughly assess the success of any prophylactic regimen.

CHAPTER 133

Vaccines, Toxoids, and Other Immunobiologics

MARY S. HAYNEY

KEY CONCEPTS

1. Live vaccines may confer life long immunity but cannot be administered to the immunosuppressed individual.
2. Inactivated and subunit vaccines and toxoids often require multiple doses to protect from infection and generally booster doses are needed following the primary series.
3. Children younger than 2 years of age are unable to mount a T-cell–independent immune responses that are elicited by polysaccharide vaccines.
4. Severely immunocompromised individuals should not receive live vaccines; and their responses to inactivated, polysaccharide, toxoid, and recombinant vaccines may be poor.
5. The childhood and adolescent immunization schedule are updated frequently and published annually. These documents can be used to develop an immunization plan for children.
6. Pneumococcal immunization is done with two different types of vaccines with the conjugate 13 valent vaccine used in infants and the pneumococcal polysaccharide vaccine used in the elderly and other individuals with high risk medical conditions.
7. Immunoglobulin (Ig) provides rapid post-exposure protection from measles, hepatitis A, varicella, and other infections that wane over time.
8. Ig adverse effects are often secondary to infusion rate. Slowing the intravenous infusion rate ameliorates chills, nausea, and fever that may develop during administration.
9. Rh_o(D) Ig prevents Rh-negative mothers from mounting an immune response against hemolytic disease of the newborn. Hemolytic disease of the newborn results when Rh-negative mothers are sensitized to the Rh(D) antigen on the red blood cells of their fetuses.

Immunization is defined as rendering a person protected from an infectious agent. Immunity to an infectious agent can be acquired by exposure to the disease, by transfer of antibodies from mother to fetus, through administration of immunoglobulin (Ig), and from vaccination. Immunization is the process of introducing an antigen into the body to induce protection against the infectious agent without causing disease. An *antigen* is a substance that induces an immune response. An *antibody* produced by the humoral arm of the immune system usually is the response that is measured as evidence of successful vaccination. However, the cellular immune response, which is much more difficult to measure, is also an important aspect of vaccine response.

This chapter introduces three groups of agents: vaccines, toxoids, and immune sera (together known as *immunobiologics*). Agents with a limited scope of use, such as agents for bioterrorism or travel, are beyond the scope of this chapter.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

PRODUCTS USED TO IMMUNIZE

Vaccines and toxoids are separate and distinct products. However, both types of products induce active immunity—that is, immunity generated by a natural immunologic response to an antigen. Vaccines can be live attenuated or inactivated. Inactivated vaccines may consist of whole or split particles derived from the pathogen. Bacterial vaccines generally are killed whole bacteria or specific bacterial antigens or conjugates. Live-attenuated vaccines induce an immunologic response more consistent with that occurring with natural infection. (1) Because the organisms in live-attenuated vaccines undergo limited replication in the vaccinated individual after administration, they may confer lifelong immunity with one dose (as does a primary natural infection). (2) Multiple doses of killed vaccines usually are needed to induce long-lasting, effective immunity. Additional doses at varying time intervals (booster doses) often are required to maintain immunity. Booster doses of such vaccines elicit memory responses from the B cells that produce immunoglobulin G (IgG). The immune system already has developed an array of antibodies to the antigen. Upon restimulation with a booster dose, the B cells, which produce the most specific antibodies against the antigen, are activated. Restimulation allows the most active antibodies against the antigen to be selected and maintained in the "immunologic memory." Thus, the booster dose results in a rapid, intense antibody response that is long lasting. Inactivated vaccines also can differ in immunity potential, depending on their composition. For example, polysaccharide vaccines tend to be poorly immunogenic in infants, whereas protein–polysaccharide conjugated vaccines of the same antigen tend to be highly immunogenic (e.g., pneumococcal polysaccharide vaccine vs pneumococcal conjugated vaccine). (3) A T cell–independent immune response is made to polysaccharide antigens that stimulate B cells directly.[1] There is no maturation or booster response with a T-cell–independent immune response, and children younger than 2 years cannot make this type of response. Protein–polysaccharide conjugate vaccines stimulate T cells and promote interactions between T cells and B cells when

producing the protective immune responses consisting of immunologic memory and high-affinity IgG.

Toxoids are inactivated bacterial toxins that generally are combined with aluminum salts to enhance their antigenicity by prolonging antigen absorption and exposure. These adjuvants also increase local tissue irritation when injected. Toxoids stimulate the production of antibodies against the bacterial toxins rather than the infecting bacterial pathogens.

Immune sera are sterile solutions containing antibody derived from human (immunoglobulin) sources. Immunoglobulins are derived from donor pools of blood plasma and are processed using cold ethanol fractionation in order to inactivate known potential pathogens. These sera are indicated for induction of passive immunity (temporary immunity to infection as a result of administration of antibodies not produced by the host; see Other Immunobiologics below).

In addition to the active component in an immunobiologic, other active and inert ingredients are often present. Suspending agents, such as water, saline, or complex fluids containing proteins (e.g., albumin), are used as the vehicle for the immunobiologic agent. Preservatives, stabilizers, and antibiotics may be added to help maintain the integrity of the product. Immunized individuals may respond with allergic reactions not to the immunobiologic agent itself but to the other components of the pharmaceutical preparation. Different manufacturers of the same immunobiologic may have different active and inert ingredients or different quantities of these ingredients in their products.

Certain vaccines manufactured by various companies are considered interchangeable. Hepatitis A, hepatitis B, and *Haemophilus influenzae* type b (Hib) conjugate vaccines for the primary series of three doses are considered interchangeable. It is preferable to use diphtheria, tetanus toxoids, and acellular pertussis (DTaP) vaccine from the same manufacturer to complete the entire primary series. However, immunization should not be delayed if the particular type of vaccine administered for the initial doses cannot be ascertained easily.[1]

In general, vaccines and toxoids must be kept refrigerated because breaking the "cold chain" may result in loss of potency. Varicella vaccine and zoster vaccines must be stored frozen. Immune sera generally should be kept refrigerated and not frozen except for lyophilized human intravenous immunoglobulin (IVIG), which can be stored at room temperature. Careful attention to appropriate storage of all vaccines and immunobiologics is absolutely imperative. Directions for appropriate storage can be found in the package inserts.

FACTORS AFFECTING RESPONSE TO IMMUNIZATION

Various factors are known to affect response to vaccines and toxoids. Viability of the antigen is an important factor (live attenuated vs inactivated), as discussed previously. Total dose also is important because there seems to exist a threshold dose above which no further increase in antibody titer is seen. The interval between immunization doses, number of doses given, or both may change immune response to an agent. Among hepatitis B vaccine nonresponders, a significant proportion of individuals mount a vaccine response when given additional doses of vaccine.[2] In contrast, additional doses of influenza vaccine are minimally effective in individuals with chronic illness.[3,4] Generally, intervals longer than those recommended between vaccine doses do not reduce immune response.[1]

The route and site of administration of the immunobiologic are important. This is best illustrated by the hepatitis B vaccine, which elicits a satisfactory antibody response when given in the deltoid muscle but not a consistent response when administered in the gluteal area. Injections should be administered at a site with little likelihood of site damage. Immunobiologics containing adjuvants should be given into a muscle mass because they can cause irritation when given subcutaneously or intradermally.[1]

Host factors influence vaccine response. Immunocompromise, increasing age, underlying disease, and genetic background have been associated with poor response rates.[5–8]

VACCINE ADMINISTRATION

Subcutaneous injections should be administered into the thigh of infants and in the upper arm area of older children and adults. A ⅝-inch, 25-gauge needle should be used, taking care not to administer the dose intradermally or intramuscularly (IM). For IM injection, the anterolateral aspect of the upper thigh (infants and toddlers) or the deltoid muscle of the upper arm (children and adults) should be used. When giving an IM injection to an adult, at least a 1-inch needle should be used for persons weighing less than 90 kg and a 1.5-inch needle for persons weighing more than 90 kg to ensure injection in the muscle.[1] The buttock should not be used because of the potential for inadequate immunologic response and the potential risk of injury to the sciatic nerve. When the buttock must be used (as for large doses of Ig), only the upper outer quadrant should be used, with the needle inserted anteriorly.

The rotavirus vaccines are administered orally. The tube of vaccine should be squeezed inside the infant's mouth toward the inner cheek until the dosing tube is empty. If the infant regurgitates or spits out the vaccine, readministration is not recommended.[9]

Live-attenuated influenza vaccine is administered intranasally. A specially designed sprayer is inserted just inside the nostril, and the dose is sprayed by depressing the plunger of the sprayer. The clip is removed from the plunger so that the second half of the dose can be administered into the other nostril. The vaccinated individual should breathe normally. The dose does not need to be repeated if the individual sneezes during or shortly after administration.[4]

Questions often arise concerning the simultaneous administration of vaccines. In general, inactivated and live-attenuated vaccines can be administered simultaneously at separate sites. If two or more inactivated vaccines cannot be administered simultaneously, they can be administered without regard to spacing between doses. Inactivated and live vaccines can be administered simultaneously or, if they cannot be administered simultaneously, at any interval between doses, except for cholera (killed) and yellow fever (live) vaccines, which should be given at least 3 weeks apart. If live vaccines are not administered simultaneously, their administration should be separated by at least 4 weeks. Live viral vaccines may interfere with purified protein derivative response; thus, tuberculin testing should be postponed 4 to 6 weeks after administration of live-virus vaccine.[1]

Simultaneous administration of Ig and live-attenuated vaccines may inhibit host antibody response because of impairment of viral replication. A dose relationship exists between administration of Ig and inhibition of immune response to a vaccine (Table 133–1). Whole blood and other blood products containing antibodies may interfere with the response to the measles, mumps, and rubella (MMR) and varicella vaccines. In any patient, if vaccination with MMR or varicella is followed by emergency Ig administration, the vaccine can be repeated or seroconversion to viral antigens can be confirmed after sufficient time has elapsed (see Table 133–1). Immunoglobulin does not interfere with the response to oral vaccines, zoster vaccine, or yellow fever vaccine.[1,10]

Simultaneous administration of inactivated vaccines along with immunoglobulins is not contraindicated. However, different sites are recommended for killed vaccine and Ig administration.

TABLE 133-1 Suggested Intervals Between Administration of Immunoglobulin and Measles- or Varicella-Containing Vaccine

Product/Indication	Dose, Including mg Immunoglobulin G (IgG)/kg Body Weight	Recommended Interval Before Measles or Varicella-Containing[a] Vaccine Administration
RSV monoclonal antibody (Synagis®)[b]	15 mg/kg intramuscularly (IM)	None
Tetanus IG (TIG)	250 units (10 mg IgG/kg) IM	3 months
Hepatitis A IG		
Contact prophylaxis	0.02 mL/kg (3.3.mg IgG/kg) IM	3 months
International travel	0.06 mL/kg (10 mg IgG/kg) IM	3 months
Hepatitis B IG (HBIG)	0.06 mL/kg (10 mg IgG/kg) IM	3 months
Rabies IG (RIG)	20 IU/kg (22 mg IgG/kg) IM	4 months
Measles prophylaxis IG		
Standard (i.e., nonimmunocompromised) contact	0.25 mL/kg (40 mg IgG/kg) IM	5 months
Immunocompromised contact	0.50 mL/kg (80 mg IgG/kg) IM	6 months
Blood tranfusion		
Red blood cells (RBCs), washed	10 mL/kg negligible IgG/kg intravenously (IV)	None
RBCs, adenine-saline added	10 mL/kg (10 mg IgG/kg) IV	3 months
Packed RBCs (Hct 65%)[c]	10 mL/kg (60 mg IgG/kg) IV	6 months
Whole blood (Hct 35%-50%)[c]	10 mL/kg (80-100 mg IgG/kg) IV	6 months
Plasma/platelet products	10 mL/kg (160 mg IgG/kg) IV	7 months
Cytomegalovirus intravenous immune globulin (IGIV)	150 mg/kg maximum	6 months
IGIV		
Replacement therapy for immune deficiencies[d]	300-400 mg/kg IV[e]	8 months
Immune thrombocytopenic purpura	400 mg/kg IV	8 months
Immune thrombocytopenic purpura	1000 mg/kg IV	10 months
Postexposure varicella prophylaxis[e]	400 mg/kg IV	8 months
Kawasaki's disease	2 g/kg IV	11 months

This table is not intended for determining the correct indications and dosages for using antibody-containing products. Unvaccinated persons might not be fully protected against measles during the entire recommended interval, and additional doses of immune globulin or measles vaccine might be indicated after measles exposure. Concentrations of measles antibody in an immune globulin preparation can vary by manufacturer's lot. Rates of antibody clearance after receipt of an immune globulin preparation also might vary. Recommended intervals are extrapolated from an estimated half-life of 30 days for passively acquired antibody and an observed interference with the immune response to measles vaccine for 5 months after a dose of 80 mg IgG/kg.

[a]Varicella-containing vaccine, as used here, does not include zoster vaccine. Zoster vaccine may be given with antibody-containing blood products.

[b]Contains antibody only to respiratory syncytial virus.

[c]Assumes a serum IgG concentration of 16 mg/mL.

[d]Measles and varicella vaccinations are recommended for children with asymptomatic or mildly symptomatic human immunodeficiency virus (HIV) infection but are contraindicated for persons with severe immunosuppression from HIV or any other immunosuppressive disorder.

[e]The investigational product VariZIG, similar to licensed VZIG, is a purified human immune globulin preparation made from plasma containing high levels of anti-varicella antibodies (immunoglobulin class G [IgG]). When indicated, health care providers should make every effort to obtain and administer VariZIG. In situations in which administration of VariZIG does not appear possible within 96 hours of exposure, administration of immune globulin intravenous (IGIV) should be considered as an alternative. IGIV also should be administered within 96 hours of exposure. Although licensed IGIV preparations are known to contain anti-varicella antibody titers, the titer of any specific lot of IGIV that might be available is uncertain because IGIV is not routinely tested for antivaricella antibodies. The recommended IGIV dose for postexposure prophylaxis of varicella is 400 mg/kg, administered once. For a pregnant woman who cannot receive VariZIG within 96 hours of exposure, clinicians can choose either to administer IGIV or closely monitor the woman for signs and symptoms of varicella and institute treatment with acyclovir if illness occurs. (CDC. A new product for postexposure prophylaxis available under an investigational new drug application expanded access protocol. MMWR 2006;55:209–210.)

Increasing the dose or number of vaccines in this circumstance is not recommended.

VACCINE STORAGE

Appropriate storage is critical to maintaining the integrity of vaccines because improperly stored vaccines can fail to protect the individuals to whom they are administered. Refrigerator temperature is defined as between 2°C and 8°C (36°F–46°F) and freezer temperature as −15°C (5°F) or colder. Inactivated vaccines are stored refrigerated. Varicella and zoster vaccines must be stored frozen. Measles-mumps-rubella vaccine can be stored in either the freezer or refrigerator. Live attenuated influenza vaccine is stored in the refrigerator. Specific storage conditions for individual vaccines can be found in the package insert.

IMMUNIZATION OF SPECIAL POPULATIONS

INFANTS

The age of the recipient is an important determining factor in vaccine and toxoid response. In the first few months of life, maternal antibodies acquired via transplacental transfer during the third trimester of gestation protect an infant. However, the maternal antibodies also inhibit the immune response to live vaccines because the circulating antibodies neutralize the vaccine before the infant has the opportunity to mount an immune response. For this reason, live vaccines are not administered until maternal antibodies have waned, generally by infant age 12 months.[1]

Premature infants should be vaccinated at the same chronologic age using the same schedule and precautions for full-term infants. The full recommended doses of vaccines should be used, regardless of age or birth weight. Breastfed infants should be vaccinated according to standard pediatric schedules.

PREGNANT WOMEN AND POST-PARTUM IMMUNIZATION

Most vaccines are pregnancy category C. As with most drugs, the vaccines are given this category assignment not because of a known risk to the fetus but because of lack of information. No birth defect has ever been attributed to vaccine exposure.[1] For example, no cases of congenital rubella syndrome from inadvertent administration of rubella vaccine to a pregnant woman have ever been reported. Universal influenza immunization is recommended for women who

will be or are pregnant during influenza season. Tetanus-diphtheria (Td) vaccine is recommended for pregnant women who have not received a Td booster in the past 10 years or requires tetanus prophylaxis with a tetanus prone wound (see Tetanus section). Although live vaccines generally are avoided because of the theoretical risk of transmission of the vaccine organism to the fetus, inactivated vaccines may be administered to pregnant women when the benefits outweigh the risks.[1] Hepatitis B, hepatitis A, meningococcal, inactivated polio, and pneumococcal polysaccharide vaccines should be administered to pregnant women who are at risk for contracting these infections.[11]

Administration of live vaccines, such as rubella or varicella, are deferred until post-partum and are routinely recommended for new mothers who do not have evidence of immunity prior to hospital discharge. These live vaccines can be administered without regard to administration of Rh_o(D) Ig in the postpartum period. Additionally, Tdap is recommended for all new mothers who have not received a tetanus dose in the past two years because household contacts are frequently implicated as the source of pertussis infection in a young infant.[12]

IMMUNOCOMPROMISED HOSTS

Vaccination in compromised hosts (e.g., those with chronic disease, such as diabetes or connective tissue disease, alcoholics, or those with cancer or HIV disease) must be individualized based on the disease state and its treatment. 4 In general, severely immunocompromised individuals should not receive live vaccines. Administration of other vaccines may be indicated, but responses may be lower than those mounted by healthy individuals, but may still confer protection.[6,8]

Patients with chronic pulmonary, renal, hepatic, or metabolic disease who are not receiving immunosuppressants can receive both live-attenuated and killed vaccines and toxoids to induce active immunity. These patients often need higher doses of vaccines or more frequent dosing to induce immunity. Generally, immunization should be considered early in the course of the disease in an attempt to induce immunity at a point when the disease is less severe.

Patients with active malignant disease can receive killed vaccines or toxoids but should not be given live vaccines. The MMR vaccine is not contraindicated for close contacts, however. Live-virus vaccines can be administered to persons with leukemia who have not received chemotherapy for at least 3 months. Vaccines should be timed so that they do not coincide with the start of chemotherapy or radiation therapy. Zoster vaccine should be administered at least 2 weeks prior to the start of immunosuppressing therapy.[10] Annual influenza vaccine should be administered 2 weeks prior to chemotherapy or between cycles.[6] If vaccines cannot be given at least 2 weeks before the start of these therapies, immunization should be postponed until 3 months after the therapy has been completed. Passive immunization with Ig can be used in place of active immunization regardless of the history of immunization.

Glucocorticoids may cause suppressed responses to vaccines. For the purposes of immunization, the immunosuppressing dose of corticosteroids is prednisone 20 mg or more daily or 2 mg/kg daily, or an equivalent dose of another steroid, for at least 2 weeks. Patients receiving long-term, alternate-day steroid therapy with short-acting agents, administration of maintenance physiologic doses of steroids (e.g., 5–10 mg/day of prednisone) topical, aerosol, intraarticular, bursal, or tendon steroid injections require no special consideration for immunization. If patients have been receiving high-dose corticosteroids or have had a course lasting longer than 2 weeks, then at least 1 month should pass before immunization with live-virus vaccines.[1]

Patients with HIV infection require special consideration. Responses to live and inactivated vaccines generally are suboptimal and decrease as the disease progresses because HIV produces defects in cell-mediated immunity and humoral immunity. The routinely recommended vaccines should be administered to children. Two doses of MMR vaccine should be administered at least 1 month apart as soon as possible after the first birthday. MMR and varicella virus should be administered only to children who have no or only moderate evidence of immunosuppression.[1] Two doses of varicella vaccine separated by 3 months are recommended only for children with no evidence of immunosuppression. Adults should receive routinely recommended vaccines. Zoster vaccine may be administered to individuals with HIV infection who do not have clinical manifestations of AIDS and have CD4 counts >200/mm^3.[1,10]

TRANSPLANT PATIENTS

Solid-Organ Transplant Patients

Organ transplantation has become routine treatment of end-stage organ disease of many causes. Although the number of organ transplants performed is severely limited by the availability of donor organs, survival of transplant recipients is increasing. Solid-organ transplant patients remain on immunosuppressive regimens for the rest of their lives. These immunosuppressive regimens result in a higher risk of infection and decrease the protection conferred by immunization.[13]

Whenever possible, transplant patients should be immunized prior to transplantation. Live vaccines generally are not given after transplantation. Post-transplantation diphtheria, tetanus, pneumococcal, and influenza vaccine responses are unpredictable. Decreased immune response has been documented following hepatitis B vaccine.

Hematopoietic Stem Cell Transplant Patients

Reimmunization of patients with hematopoietic stem cell transplantation is necessary because antibody concentrations wane rapidly. Annual influenza immunization may begin as soon as 6 months after successful engraftment. Reimmunization with inactivated vaccines should begin approximately 12 months after hematopoietic stem cell transplantation. Hematopoietic stem cell transplant recipients are at increased risk for fulminant infection with encapsulated bacteria so PPSV23 and Hib vaccines are recommended. Less evidence exists in support of meningococcal conjugate vaccine or pneucmococcal conjugate vaccine administration. MMR can be administered at 24 months. Varicella vaccine is not routinely recommended but can be considered on a case-by-case basis. Immunization of household contacts and healthcare workers also is necessary.[1]

CONTRAINDICATIONS AND PRECAUTIONS

There are few contraindications to the use of vaccines except those outlined earlier. The contraindications include a history of anaphylactic reactions to the vaccine or a component of the vaccine. Unexplained encephalopathy occurring within 7 days of a dose of pertussis vaccine is a contraindication to future doses of pertussis vaccines. Immunosuppression and pregnancy are temporary contraindications to live vaccines. An interval of time must elapse based on the dose of Ig before a live vaccine can be administered (see Table 133–1). Precautions for DTaP administration include hypotonic hyporesponsive episode, fever of 40.5°C (104.9°F) or greater, crying lasting more than 3 hours within 48 hours of a previous

dose, and seizures with or without fever within 3 days after a dose.[1] Generally, mild to moderate local reactions, mild acute illnesses, concurrent antibiotic use, prematurity, family history of adverse events, diarrhea, and lactation or breastfeeding are not contraindications to immunization.

OBTAINING AN IMMUNIZATION HISTORY

An immunization history should be obtained from every patient, regardless of the reason for the healthcare visit. Ideally, any history provided by the patient from memory should be verified by reviewing the patient's personal written immunization record or a database that contains the complete immunization history. State-based or other public health jurisdiction-based immunization registries has been developed to improve immunization coverage by allowing healthcare providers access to records at any contact with the healthcare system. Registries are aimed primarily at facilitation of childhood immunization records.[14] If an official written record is not available, patient characteristics (e.g., military service, travel history, and occupation) may provide clues to the immunization history. Serologic testing for immunity against certain diseases can provide specific information but is used routinely for only a few selected diseases (e.g., measles, rubella, hepatitis A and B, and varicella) and selected circumstances (e.g., employment in a healthcare facility). If a written record does not exist, one should be generated at the time of initiation of immunization. Patients without a written record should be considered susceptible, and an immunization program started and completed unless a serious adverse reaction occurs. As a general rule, the risks associated with overimmunization are minimal relative to the risks associated with contracting vaccine-preventable diseases.[1]

Every healthcare visit, regardless of its purpose, should be viewed as an opportunity to review a patient's immunization status and to administer needed vaccines. Immunization is perhaps the most cost-effective health intervention available. Each visit should include assessment of individuals' vaccine needs, administration of indicated agents, and documentation of immunization histories. The outcome measurement of what percentage of patients in a particular practice site is completely immunized is extremely important because the benefits of optimal vaccine use extend beyond the individual patient to the public as a whole.

NATIONAL VACCINE INJURY COMPENSATION PROGRAM

The National Childhood Vaccine Injury Act of 1986 was passed by the U.S. Congress in response to reports of vaccine side effects and liability concerns of vaccine manufacturers and healthcare providers. With vaccine safety being questioned and manufacturers ceasing the development and marketing of vaccines, the National Vaccine Injury Compensation Program was implemented to offer a no-fault alternative means to compensate victims for injury following vaccination. The program offers liability protection to manufacturers and an efficient means of recovering damages for individuals potentially injured by vaccines. Compensation for vaccine-related injuries is outlined in the Health Resources and Services Administration's Vaccine Injury Table (*http://www.hrsa.gov/vaccinecompensation/table.htm*). Healthcare providers must report all events requiring medical attention within 30 days of vaccination to the Vaccine Adverse Event Reporting System (VAERS), which serves as a central depot for vaccine-related adverse effects. Only a temporal association between the adverse event and vaccine administration needs to be made. No adverse event rates can be determined because only the number of adverse events reported is known; the number of vaccines administered is not known. This database can be used to determine changes in the frequencies of adverse events, to evaluate risk factors for adverse events, and to find rare adverse events.[15] VAERS report forms can be obtained by calling 1-800-822-7967, or reports can be made online at *https://vaers.hhs.gov/esub/index*.

USE OF VACCINES AND TOXOIDS

5 The Appendices show the recommended schedules for routine immunization of children and adults. All states require children to be fully immunized prior to entering elementary school; however, optimal protection is achieved by immunizing at the recommended ages, which requires special attention to children younger than 2 years. Adults and adolescents also require vaccination and often are unaware of this need. An early adolescent preventive health visit is recommended. This visit is an opportunity to catch up on missed immunizations and to administer meningococcal conjugate, Tdap, and, for females, human papillomavirus (HPV) vaccines. Adults should receive routine Td or Tdap boosters and be immune to measles, mumps, rubella, and varicella by either immunization or history of infection. Older adults need an annual influenza vaccine after age 50 years, zoster vaccine after age 60 years, and pneumococcal polysaccharide vaccine after age 65 years. Certain individuals with conditions or lifestyles that put them at high risk for vaccine-preventable diseases also should be immunized as described in the following text and outlined in the immunization schedules in the appendices.

TOXOIDS

DIPHTHERIA TOXOID ADSORBED

Diphtheria is an acute illness caused by the toxin released by a *Corynebacterium diphtheriae* infection. The toxin inhibits cellular protein synthesis, and membranes form on mucosal surfaces. Systemic toxemia can result in myocarditis, neuritis, and thrombocytopenia. Membrane formation can cause respiratory obstruction, and significant toxin absorption can lead to severe illness and death.

Diphtheria toxoid adsorbed is a sterile suspension of modified toxins of *C. diphtheriae* that induces immunity against the exotoxin of this organism. Two strengths of diphtheria toxoid are available in the United States: pediatric strength (D) and adult strength (d), which contains less antigen. The widespread use of diphtheria toxoid essentially has eliminated diphtheria from the United States.

Primary immunization with diphtheria toxoid (D) is indicated for children older than 6 weeks. The toxoid is given in combination with tetanus toxoid and acellular pertussis vaccine (as DTaP or in combination with additional childhood vaccines that have been licensed to decrease the number of injections required to complete the childhood immunization recommendations) at age 2, 4, and 6 months. Additional doses are given at age 15 to 18 months and again at age 4 to 6 years.[16] Completing the primary diphtheria toxoid immunization series usually induces immunity of at least 10 years' duration in 90% of persons. Booster doses should be given every 10 years.

For unimmunized adults, a complete three-dose series of diphtheria toxoid should be administered, with the first two doses given at least 4 weeks apart and the third dose given 6 to 12 months after

the second. The combined Td preparation is recommended for adults because it contains less diphtheria toxoid than the pediatric dose and is associated with fewer reactions to the diphtheria component. If the adult is 64 years of age or younger, one of the vaccine doses in this series should be Tdap.[17] All adults should receive booster doses of Td every 10 years. Adverse effects of diphtheria toxoid include mild to moderate tenderness, erythema, and induration at the injection site. Systemic reactions occur very rarely.

TETANUS TOXOID, TETANUS TOXOID ADSORBED, AND TETANUS IMMUNOGLOBULIN

Tetanus is a severe acute illness caused by the exotoxin of *Clostridium tetani*. Tetanus is the only vaccine-preventable disease that is not contagious. It is acquired from the environment. Sustained muscle contractions are characteristic of tetanus. Tetanus toxin interferes with neurotransmitters that promote muscle relaxation, leading to continuous muscle spasms.[17] Death can be due to the tetanus toxin itself or secondary to a complication such as aspiration pneumonia, dysregulation of the autonomic nervous system, or pulmonary embolism.

Tetanus toxoid and tetanus toxoid adsorbed (adsorbed onto aluminum hydroxide, phosphate, or potassium sulfate to increase antigenicity) are sterile suspensions of the toxoid derived from *C. tetani*. Both toxoids are used to promote active immunity against tetanus; however, tetanus toxoid adsorbed is the preferred agent because it elicits a greater immune response and is associated with fewer adverse reactions.

A series of three 0.5-mL doses of tetanus toxoid elicits protection in virtually all individuals. Primary vaccination provides protection for at least 10 years.[12,17,18] Additional doses of tetanus toxoid (combined with diphtheria toxoid, i.e., Td) are recommended as part of wound management if a patient has not received a dose of tetanus toxoid within the preceding 5 years. For minor or clean wounds, no dose is given. Table 133–2 summarizes these recommendations. Tetanus Ig should be given to individuals who have received fewer than three doses of tetanus toxoid and have more serious wounds. It can be administered with tetanus toxoid, provided that separate syringes and separate injection sites are used.

In children, primary immunization against tetanus usually is offered in conjunction with diphtheria and pertussis vaccination (using DTaP or a combination vaccine that includes other antigens used to decrease the number of injections to complete the childhood immunization schedule). A 0.5-mL dose is recommended at age 2, 4, 6, and 15 to 18 months, but the first dose can be administered as early as age 6 weeks.[16] In children 7 years and older and in adults who have not been immunized previously, a series of three 0.5-mL doses of Td is administered IM initially. The first two doses are given 1 to 2 months apart, and the third dose is recommended at 6 to 12 months after the second dose. Boosters are recommended every 10 years, and unless there is contraindication to diphtheria toxoid, Td should be used. Tetanus toxoid can be given simultaneously with other killed and live vaccines, and, if indicated, it can be given to immunosuppressed patients.

Adverse reactions to tetanus toxoid include mild to moderate local reactions at the injection site, such as warmth, erythema, and induration. Rarely, fever, malaise, aches and pains, or neurologic disorders have been reported. In general, major local reactions occur within 2 to 8 hours of administration to patients with high serum tetanus antitoxin levels. This type of reaction is indicative of high preexisting antibody concentrations, and additional doses of toxoid should not be given any sooner than 10 years. Local reactions do not limit the use of the toxoid for further dosing.

TABLE 133-2 Tetanus Prophylaxis

Vaccination History	Clean, Minor		All Other	
	Td[a]	TIG	Td[a]	TIG
Unknown or fewer than three doses	Yes	No	Yes	Yes
Three or more doses	No[a,b]	No	No[a,c]	No

[a]A single dose of Tdap should be used for the next dose of tetanus-diphtheria toxoid for individuals aged 10 or 11 years to 64 years.
[b]Yes, if more than 10 years since last dose.
[c]Yes, if more than 5 years since last dose.

Tetanus immunoglobulin is a sterile, concentrated, nonpyrogenic solution of immunoglobulins prepared from hyperimmunized humans. It is used to provide passive immunity to tetanus after the occurrence of traumatic wounds in nonimmunized or suboptimally immunized persons (see Table 133–2). A dose of 250 to 500 units IM should be administered. When administered with tetanus toxoid, separate sites for administration should be used. Tetanus immunoglobulin also is used for treatment of tetanus. In this setting, a single dose of 3,000 to 6,000 units IM is administered.

Adverse effects of tetanus immunoglobulin include pain, tenderness, erythema, and muscle stiffness at the injection site, which may persist for several hours. Systemic reactions occur rarely. IV administration has been associated with severe adverse reactions and is not recommended.

VACCINES

HAEMOPHILUS INFLUENZAE TYPE B VACCINES

Before 1995, Hib was responsible for thousands of cases of serious illnesses (e.g., meningitis, epiglottitis, pneumonia, sepsis, and septic arthritis). The incidence of Hib disease has declined more than 99% since introduction of the conjugate vaccines based on the organism's capsular substance, polyribosylribitol phosphate (PRP).[19]

The Hib vaccines used are conjugate products consisting of either a polysaccharide or an oligosaccharide of PRP covalently linked to a protein carrier. The protein carrier is important because it provides for T-lymphocyte–dependent immunologic response, whereas earlier Hib vaccines that consisted of only unconjugated PRP elicited a response that was T-cell independent. T-cell involvement in the response provides for (a) a greater antibody response regardless of the age of the patient receiving the vaccine, (b) immunologic response at an earlier age (including infants), and (c) a booster effect on subsequent exposure to the Hib capsule, whether through revaccination or natural exposure. The protein carrier is not considered a vaccine and should not be substituted for immunization against tetanus, diphtheria, or *Neisseria meningitidis*.

Hib conjugate vaccines are indicated for routine use in all infants and children younger than 5 years. Additionally, these three products differ in their immunogenicity and schedule of administration (Table 133–3). The primary series of Hib vaccination consists of a 0.5-mL IM dose at ages 2, 4, and 6 months if HbOC (HibTITER) or PRP-T (ActHIB) is used. If PRP-OMP is being used, the primary series consists of doses given at ages 2 and 4 months. The series should not be initiated in an infant younger than 6 weeks. Although use of one product for the entire primary series is desirable, adequate protection is achieved even when different products are used during the initial doses. Following the primary series, a booster dose is recommended at age 12 to 15 months. Any of the Hib conjugate vaccines are suitable for the booster dose regardless of which conjugate was used for the primary series of doses.[16]

TABLE 133-3 *Haemophilus influenzae* Type b Conjugate Vaccine Products

Vaccine	Trade Name	Protein Carrier
PRP-T	ActHIB (Sanofi Pasteur)	Tetanus toxoid
PRP-OMP	PedvaxHIB (Merck)	*Neisseria meningitides* serogroup B outer membrane protein
PRP-T	Hiberix (Glaxo Smith Kline)	Tetanus toxoid (booster only)

The polysaccharide is polyribosylribitol-phosphate (PRP).

Schedules are more complex for infants who do not begin Hib immunization at the recommended age or who have fallen behind in the immunization schedule. For infants 7 to 11 months of age who have not been vaccinated, three doses of HbOC, PRP-OMP, or PRP-T should be given: two doses spaced 4 weeks apart and then a booster dose at age 12 to 15 months (but at least 8 weeks since the second dose). For unvaccinated children ages 12 to 14 months, two doses should be given, with an interval of 2 months between doses. In a child older than 15 months, a single dose of any of the four conjugate vaccines is indicated.[16] The American Academy of Pediatrics has made recommendations for children with lapsed immunization. For infants 7 to 11 months who have received one or two doses of Hib vaccine, one dose of vaccine with a booster dose at least 8 weeks later at age 12 to 15 months should be given. For children 12 to 14 months who received two doses, a single dose is indicated. If the child received only one dose before age 12 months, two additional doses separated by 8 weeks should be given. A single dose of vaccine is needed for a child 15 to 59 months old who has received any incomplete schedule.[16]

Vaccines for Hib are recommended for routine use only for patients up to age 59 months; beyond this age, most individuals will have natural immunity to Hib infection. Patients with certain underlying conditions (e.g., HIV infection, IgG_2 subclass deficiency, sickle cell disease, splenectomy, and hematopoietic stem cell transplants and those receiving chemotherapy for malignancies) are at higher than normal risk for Hib infection, and use of at least one dose of vaccine in these patients should be considered, although efficacy data in most of these situations are lacking.[1,20]

Adverse reactions to the Hib vaccine are uncommon. Erythema and induration at the injection site occur in approximately 25% of children and resolve within 24 hours. Fever, diarrhea, and vomiting are reported occasionally. Fever greater than 38°C (100.4°F) is reported in 2.4% of children.

HEPATITIS VACCINES

Information on vaccination for viral hepatitis is given in Chapter 47.

HUMAN PAPILLOMAVIRUS VACCINE

HPV infections are the most common sexually transmitted infections, with the highest prevalence of infection in sexually active young adults.[21] Although more than 120 different HPV types have been identified, at least 40 different types of HPV infect the anogenital tract. These 40 different viruses are grouped into low-risk and high-risk types. Low-risk types can cause genital warts and mild abnormalities on Papanicolaou (Pap) tests. Ninety percent of all cases of genital warts are caused by types 6 and 11. As many as 18 types are considered high risk. They cause abnormal Pap test results and may lead to cancer of the cervix, vulva, vagina, anus, or penis. Types 16 and 18 cause about 70% of all cervical cancers. High-risk HPV infections are necessary but not sufficient for the development of cervical cancer and for the majority of other anogenital and oral squamous cell cancers.

A bivalent human papillomavirus vaccine (Cervarix, GSK) containing virus-like particles for types 16 and 18 was licensed in late 2009. The quadrivalent vaccine (Gardasil, Merck Vaccines) is directed against cervical cancer-causing types 16 and 18 and types 6 and 11. ACIP recommends either of these HPV vaccine preparations for the prevention of cervical cancer and precancerous lesions. No head-to-head comparison of these vaccines is available, but both vaccines are very efficacious for the prevention of precancerous lesions caused by types 16 and 18.[22] Both vaccines offer some protection against oncogenic nonvaccine strains too.[23–25] Both vaccines are administered as a three dose series using a harmonized schedule of 0, 1 to 2, and 6 months. The vaccines are recommended for females aged 11 to 12 years and for all females aged 13 to 26 years. Although administration of these vaccines before sexual debut is preferable, the vaccines can be administered without regard to history of sexual activity.

The quadrivalent HPV vaccine is licensed for the prevention of genital warts in males aged 9 to 26 years. Types 6 and 11 cause approximately 90% of genital warts. Although not considered a serious disease, the direct medical cost of genital warts is about $200 million annually, and genital warts have an impact on quality of life.[26] Additionally, approximately one fourth to one third of oropharyngeal cancers are associated with a high risk HPV infection.[27] No data on the usefulness of the vaccine for the prevention of these cancers are available yet. ACIP stated that HPV4 may be given to males aged 9-26 years of age but stopped short of a recommendation for it. The vaccine is effective for the prevention of genital warts, but the cost-effectiveness of the vaccine series for males is a major hurdle.

The vaccines are well tolerated, with injection-site reactions and systemic reactions (e.g., headache and fatigue) occurring as commonly in immunized individuals as in the groups receiving placebo. Although syncope is possible with any immunization, the target population of young women have a higher incidence of syncope, including with administration of the HPV vaccine.[27,28]

These effective vaccines is an important advance, but the need for a Pap test for cervical cancer screening remains. Surveillance for duration of protection conferred by the vaccine series is ongoing; the need for future booster doses is not yet known.

INFLUENZA VIRUS VACCINE

Information on vaccination for influenza is given in Chapter 118.

MEASLES VACCINE

Measles (rubeola) is a highly contagious viral illness characterized by rash and high fever. Complications of measles infections include severe diarrhea, otitis media, pneumonia, and encephalitis. Measles results in one to two deaths per 1,000 cases, with a much higher death rate in developing countries. With widespread vaccination, measles is on the verge of elimination from the Western Hemisphere.

The measles vaccine is a live-attenuated viral vaccine that produces a subclinical, noncommunicable infection. Approximately 95% of vaccine recipients seroconvert after a single dose, and most individuals are protected for life.[25] Most persons who do not respond to the initial dose of measles vaccine will seroconvert after receiving a second dose, and this forms the basis for the two-dose vaccine strategy that was implemented in the United States in 1989.

The measles vaccine is administered subcutaneously as a 0.5-mL dose in the arm (or in the thigh if the patient is younger than 15 months). The vaccine is administered routinely for primary immunization to persons 12 to 15 months of age, usually as the MMR vaccine. The measles vaccine is not administered earlier

than 12 months (except in certain outbreak circumstances) because persisting maternal antibody that was acquired transplacentally late in gestation can neutralize the vaccine virus before the vaccinated person can mount an immune response. A second dose of MMR or MMRV is recommended when children are 4 to 6 years old.[16] The second dose of vaccine results in seroconversion in 95% of individuals who were first-dose nonresponders.

Measles-containing vaccine should not be given to pregnant women or immunosuppressed patients. The one exception is HIV-infected patients, who are at very high risk for severe complications if they develop measles.[26] Persons with HIV infection who have never had measles or have never been vaccinated against it should be given measles-containing vaccine unless there is evidence of severe immunosuppression. The second dose should be given 1 month later rather than waiting for entry to school.

Recent administration of Ig interferes with measles vaccine response, so the recommended interval between the Ig and vaccine is determined by the dose of Ig (see Table 133–1).[1] Live vaccines not administered during the same visit must be delayed for at least 30 days following measles or MMR vaccine. Live measles vaccine may suppress a positive tuberculin skin test for up to 6 weeks postadministration.[1] Persons with a history of anaphylactic reaction to egg protein were considered to be at high risk for serious reactions to measles vaccine, a product derived from chick embryo fibroblasts. However, the risk of measles vaccination to egg-allergic patients is exceedingly low. Therefore, individuals requiring the measles vaccine should receive it regardless of a history of egg allergy.[25] A history of serious neomycin hypersensitivity remains a contraindication to measles vaccine use because each 0.5-mL dose contains 25 mcg neomycin. Finally, mild febrile illness and upper respiratory tract infections are not contraindications to vaccination.[25]

Measles vaccination is indicated in all persons born after 1956 or in those who lack documentation of wild virus infection by either history or antibody titers. Persons who received killed measles vaccine alone, who were given live vaccine within 3 months of receiving killed vaccine, or who received a vaccine of unknown type between 1963 and 1967 should be revaccinated. Two doses of a measles-containing vaccine are required for college students and healthcare workers who were born in 1957 or later. If two doses are needed (the person has never been vaccinated), the doses should be given at least 1 month apart.[27]

The measles vaccine has an excellent safety record. The most common side effect following vaccination is fever, which occurs in 5% to 15% of vaccinees. Transient generalized rash may occur in approximately 5% of vaccine recipients. These reactions generally appear 5 to 12 days postvaccination and last 2 to 5 days. Other adverse effects, such as headache, cough, sore throat, eye pain, malaise, and transient thrombocytopenia, occur less frequently. Local reactions at the injection site are rare but may occur in subjects who have been vaccinated previously with killed vaccine. After extensive study, no association between MMR vaccination and the development of autism has been made.[28]

MENINGOCOCCAL POLYSACCHARIDE AND CONJUGATE VACCINES

N. meningitidis is a leading cause of meningitis and sepsis in children and young adults in the United States. College freshmen, particularly those living in dormitories or residence halls, are at modestly increased risk for invasive meningococcal disease compared with the rest of the population in this age group.[29]

Two meningococcal conjugate vaccines combining the same serotypes are licensed for use in individuals aged 2 to 55 years old (Menaetra®, Sanofi-Pasteur) or 11 to 55 years old (Menveo®, Novartis). A quadrivalent vaccine containing capsular polysaccharides for serotypes A, C, Y, and W-135 has been available since the early 1970s. A conjugate vaccine containing the same serotypes was licensed for use in individuals 2 to 55 years old. Although serogroup B causes approximately one third of all cases, it has not been incorporated into the vaccine because group B polysaccharide is not immunogenic. Either meningococcal conjugate vaccine is recommended for all children 11 to 12 years old and others at high risk for invasive meningococcal infection, including high school students and college freshmen who live in dormitories. The meningococcal polysaccharide vaccine is indicated in high-risk populations, such as those exposed to the disease, those in the midst of uncontrolled outbreaks, travelers to areas with epidemic or hyperendemic meningococcal disease, and individuals who have terminal complement component deficiencies or asplenia. The polysaccharide preparation can be used for the immunization of college students and adults between 20 and 55 years of age, but the conjugate vaccine is preferred.[29]

Meningococcal polysaccharide vaccine is administered subcutaneously as a 0.5-mL dose. Meningococcal conjugate vaccine is administered by IM injection. Reimmunization at 5-year intervals should be considered for individuals who remain at high risk for invasive meningococcal disease.[30]

Injection-site reactions are the most common adverse effects following administration of either the meningococcal conjugate or polysaccharide vaccine.

MUMPS VACCINE

Mumps is a viral illness that classically causes bilateral parotitis 16 to 18 days after exposure. Fever, headache, malaise, myalgia, and anorexia may precede the parotitis. Serious complications are rare but more common in adults.

The mumps vaccine is a lyophilized live-attenuated vaccine prepared from chick embryo cultures. Each 0.5-mL dose of the vaccine also contains neomycin 25 mcg. The vaccine is available alone or in combinations with measles, rubella (as MMR), and varicella (MMRV) vaccines.

The vaccine is administered as a 0.5-mL subcutaneous injection in the upper arm. Dosing recommendations coincide with those for measles vaccine, with the first dose administered at age 12 to 15 months and the second dose prior to the child's entry into elementary school. Two doses of mumps-containing vaccine are recommended for school-aged children, international travelers, students in post-high school educational institutions, and healthcare workers born after 1956.[31] A single dose of vaccine is acceptable documentation of immunity to mumps for other adults considered at lower risk of mumps infection, including adults born after 1956 and those with an uncertain history of wild virus infection.

Mumps vaccine should not be given to pregnant women or immunosuppressed patients.[1] Anaphylactic reactions to mumps-containing vaccines are very rare and generally not associated with hypersensitivity to eggs. Therefore, egg allergy is not a contraindication to vaccination. The effect of Ig preparations on mumps vaccine response is unknown, but the response to measles, rubella, and varicella is compromised if the vaccine is administered after immunoglobulins. The recommended interval between the Ig and vaccine is determined by the dose of Ig (see Table 133–1).[1] The vaccine should not be given to individuals with anaphylactic reactions to neomycin.

Serious adverse reactions to the vaccine are reported rarely. Parotitis, rash, pruritus, and purpura occur rarely. Local reactions, including soreness, burning, and stinging, may occur at the injection site.

PERTUSSIS VACCINE

Pertussis is caused by a bacterial infection with *Bordetella pertussis.* The illness is characterized by paroxysms of coughing to expel thick mucus. At the end of every burst, a long inspiratory effort results in the traditional "whooping" sound. Children will often become cyanotic during the coughing spasm and be exhausted or vomit at the end of the attack. It is during this stage when pertussis is usually diagnosed. Adolescents and adults with pertussis experience similar symptoms, though typically not nearly as severe as infants and young children. Adults are less likely to "whoop" in the paroxysmal stage; in fact their cough can be so minor that it is difficult to distinguish from other common respiratory infections. Prior to the availability of a vaccine, pertussis was a common childhood infection and was a significant cause of childhood mortality. Pertussis is most contagious in the early stage of the disease, can infect people of all ages, but is most serious in infants and young children.[17,18]

Acellular pertussis vaccines contain components of the *B. pertussis* organism. All acellular vaccines contain pertussis toxin, and some contain one or more additional bacterial components (e.g., filamentous hemagglutinin, pertactin [a 69-kDa outer membrane protein], and fimbriae types 2 and 3). Acellular pertussis vaccine is recommended for all doses of the pertussis schedule at 2, 4, 6, and 15 to 18 months of age. A fifth dose of pertussis vaccine is given to children 4 to 6 years of age.[16] Pertussis vaccine is administered in combination with diphtheria and tetanus (DTaP). Administration of an acellular pertussis–containing vaccine is also recommended for adolescents once between ages 11 and 18 years. Also, adults up to age 64 years should receive a pertussis-containing vaccine with their next dose of Td toxoids.[17,18]

Local administration site reactions are relatively common. Systemic reactions, such as moderate fever, occur in 3% to 5% of vaccinees. Very rarely, high fever, febrile seizures, persistent crying spells, and hypotonic hyporesponsive episodes occur following vaccination. Allergy to a vaccine component and encephalopathy without known cause within 7 days of a pertussis vaccine are contraindications to future doses of vaccine.

PNEUMOCOCCAL VACCINES

Streptococcus pneumoniae is a common pathogen with a range of manifestations, including asymptomatic upper respiratory tract colonization, sinusitis, acute otitis media, pharyngitis, pneumonia, meningitis, and bacteremia. Rates of invasive infections are highest in children younger than 2 years and in the elderly.[32] Invasive pneumococcal infections cause approximately 40,000 deaths annually. Most of the deaths occur in the elderly or in those with underlying medical conditions.[33] Approximately half the deaths could be preventable by vaccine. Two pneumococcal vaccine preparations, PCV13 and 23-valent pneumococcal polysaccharide vaccine (PPV23) are available. The vaccines have different indications and are not interchangeable.

Pneumococcal Polysaccharide Vaccine

Pneumococcal polysaccharide vaccine (Pneumovax 23) is a mixture of highly purified capsular polysaccharides from 23 of the most prevalent or invasive types of *S. pneumoniae* seen in the United States. Serotypes included are 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F. These 23 types represent 85% to 90% of all blood isolates and 85% of pneumococcal isolates from other generally sterile sites seen in the United States. The vaccine is administered IM or subcutaneously as a single 0.5-mL dose. Each 0.5-mL dose of vaccine contains 25 mcg of each polysaccharide type dissolved in isotonic saline solution (for a total of 575 mcg polysaccharide) and 0.25% phenol as preservative.[33]

6 PPSV23 is recommended for the following individuals:[33]

- Persons 65 years and older (if an individual received vaccine more than 5 years earlier and was younger than 65 years at the time of administration, revaccination should be given)
- Persons aged 2 to 64 years with a chronic illness (congestive heart failure, cardiomyopathy, chronic pulmonary disease, diabetes, alcoholism, liver disease)
- Persons aged 2 to 64 years with functional or anatomic asplenia (when splenectomy is planned, PPSV23 should be given at least 2 weeks before surgery; a single revaccination is recommended at 5 years in subjects older than 10 years and at 3 years in subjects younger than 10 years)
- Persons aged 2 to 64 years of age living in environments where the risk of invasive pneumococcal disease or its complications is increased (this does not include daycare center employees and children)
- Persons aged 19 to 64 years who smoke cigarettes or have asthma[34]
- Persons with cochlear implants[35]

PPSV23 is recommended for immunocompromised persons 2 years and older with (a) HIV infection, (b) leukemia, (c) lymphoma, (d) Hodgkin disease, (e) multiple myeloma, (f) generalized malignancy, (g) chronic renal failure or nephrotic syndrome, (h) patients receiving immunosuppressive therapy including corticosteroids, and (i) organ and bone marrow transplant recipients. A single revaccination should be given if 5 years or more have passed since the first dose in subjects older than 10 years. In subjects 10 years of age and younger, revaccination should be given 3 years after the previous dose.

PPSV23 induces type-specific antibodies (T-cell–independent mechanisms) with a twofold rise within 2 to 3 weeks in 80% of young healthy adults. No correlation of antibody levels and protection has been determined. Antibody levels to these strains remain elevated for at least 5 years. In certain individuals, these levels decline within 10 years. Children may be protected for only 3 to 5 years. Elderly individuals and patients with chronic disease may have lower antibody levels produced with the vaccine. Children younger than 2 years do not respond adequately to the vaccine.

A number of other groups, including immunocompromised patients (e.g., leukemia, lymphoma, and multiple myeloma), dialysis patients, and patients with acquired immune deficiency syndrome, have reduced antibody production with the vaccine. Asymptomatic HIV-infected patients respond sufficiently to the vaccine. Patients with Hodgkin disease respond to the vaccine better before splenectomy, chemotherapy, or radiation therapy.

PPSV23 vaccine efficacy has been debated in the literature. Although prelicensure trials in young, healthy gold miners in South Africa showed a reduction in nonbacteremic disease rates, randomized clinical trials performed in the postmarketing period on elderly persons with chronic disease did not confirm these findings.[33] A large study of elderly individuals demonstrated a decreased risk of pneumonia caused by *S. pneumoniae* in vaccinated individuals but showed no change in the risk of community-acquired pneumonia even though most community-acquired pneumonias are caused by *S. pneumonia*.[36] For invasive disease, reduction rates of 56% to 81% with the vaccine have been shown. Adults hospitalized with community-acquired pneumonia are significantly less likely to die if they have been immunized. In addition, immunized patients were less likely to have respiratory failure and had hospitalization stays that were shorter by 2 days.[37]

A meta-analysis of nine randomized controlled trials concluded that the vaccine was efficacious in reducing the frequency of bacteremic pneumococcal disease among adults in low-risk groups and that the vaccine was cost-effective.[33]

PPSV23 safety is well documented. Local reactions occur frequently within the first 48 hours and generally are mild. Local erythema and induration (30%), local discomfort (40%), and local swelling (3%) are the side effects observed most commonly. Revaccination has been associated with self-limited injection-site reactions more commonly than after the first dose.[38] Severe systemic reactions occur rarely and consist of weakness, myalgia, headache, photophobia, chills, and fever.

Pneumococcal Conjugate Polysaccharide Vaccine

Invasive pneumococcal disease occurs even more frequently in children younger than 2 years than in those older than 65 years. The infection ranges goes from nasopharyngeal carriage to bacteremia and meningitis. Because of the lack of immune responsiveness in children younger than 2 years when exposed to polysaccharide vaccines, a conjugate vaccine was developed to protect young children from certain strains of *S. pneumoniae*.

A 13 valent vaccine (Prevnar-13) is available for use in children. This vaccine contains the conjugated capsular polysaccharides of serotypes 1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F, which cause the vast majority of pediatric pneumococcal bacteremias in the United States.[39,40] The vaccine elicits a primary T-cell–dependent antibody response with the first dose and an immunologic memory effect after four doses. In clinical use, the vaccine is associated with a dramatic decline in invasive disease not only in immunized young children but also in individuals in all age groups.[32]

8 PCV13 is administered as a 0.5-mL IM injection at 2, 4, and 6 months of age and between 12 and 15 months of age. PCV13 also should be used in older children aged 24 to 59 months who are at high risk. Children with sickle cell disease or splenic dysfunction, HIV infection, immunocompromising conditions, or chronic illnesses should be immunized. PPV23 can be used in conjunction with PCV13. PPV23 should be administered after age 2 years and at least 2 months after the last dose of PCV13.

The vaccine series generally is well tolerated. Injection-site reactions and fever are the most commonly reported adverse effects.[52] Widespread use of conjugated pneumococcal vaccines in infants and young children has resulted in a decreased incidence of invasive pneumococcal disease in the entire population.[39]

POLIOVIRUS VACCINES

Poliomyelitis is a contagious viral infection that usually causes asymptomatic infection; however, in its serious form it causes acute flaccid paralysis. Poliovirus is spread via the fecal–oral route. The virus replicates in the upper respiratory tract, gastrointestinal tract, and local lymphatics. The vast majority of polio infections are subclinical and asymptomatic. Indigenous polio has been absent from the United States since 1979, and the last case in Western Hemisphere was reported in 1991. Global eradication efforts are entering the final stages, and the eradication of polio should be accomplished in the next few years.

An inactivated trivalent vaccine developed by Jonas Salk was licensed for use in 1955. In 1987, an enhanced-potency IPV was introduced and has replaced the original inactivated vaccine. A live-attenuated oral polio vaccine (OPV) was developed by Albert Sabin in 1962. OPV was the primary immunizing agent for poliovirus infection. Widespread OPV use is responsible for eradication of wild-type polio in most of the world. However, with no poliovirus circulation in the United States for years, IPV is the recommended vaccine for the primary series and booster dose for children. OPV will continue to be used in areas of the world that have circulating poliovirus. The CDC maintains a stockpile of OPV to be used only in case of an outbreak.[42]

The IPV series is administered routinely to children at ages 2, 4, and 6 to 18 months, and 4 to 6 years. Protective antibodies to all three serotypes develop in 90% to 100% of children after two doses of vaccine. After three doses, 99% to 100% develop protective immunity, and the fourth dose results in long-term immunity.[42]

Primary poliomyelitis immunization is recommended for all children up to age 18 years. Primary immunization of adults over age 18 years is not recommended routinely because a high level of immunity already exists in this age group and the risk of exposure in developed countries is exceedingly small. However, unimmunized adults who are at increased risk for exposure because of travel, residence, or occupation should receive IPV series. Incompletely immunized adults or children should complete the series of IPV regardless of the interval since initiation of primary immunization. Adults do not need a booster dose routinely unless they are at increased risk of exposure (travel), in which case a single dose of IPV can be given.[55]

Allergies to any component of IPV, including streptomycin, polymyxin B, and neomycin, are contraindications to vaccine use. No serious side effects are attributable to IPV. Pregnant women should be given IPV only if there is a clear need, such as women who will be traveling or living in an area with endemic or epidemic poliovirus. IPV is recommended for immunodeficient individuals and their household contacts. Although the response may be lower, some protection against infection may be conferred.

The routine use of OPV in the United States has been discontinued because OPV is rarely associated with vaccine-associated paralytic poliomyelitis in vaccinees (1 in 6.2 million doses) or contacts (1 in 7.6 million doses). Because individuals with primary immune deficiency are at increased risk for this adverse reaction, OPV is not recommended for persons who are immunodeficient or for normal individuals who reside in a household with an immunocompromised person. The use of OPV is reserved for polio outbreak control.[42]

RABIES VACCINE

Rabies is a virtually universally fatal infection in humans. Although all mammals are susceptible to rabies, carnivorous mammals are reservoirs of the virus and responsible for persistence of the virus in nature. In the United States, most human cases of rabies are from exposure to rabid bats, but raccoons, foxes, skunks, and coyotes are also associated with possible exposure. Worldwide, canines are the primary vectors. Transmission of rabies can occur via percutaneous, permucosal, or airborne exposure to the rabies virus. Circumstances favoring such transmission include animal bites and attacks and contamination of scratches, cuts, abrasions, and mucous membranes with saliva or other infectious material (brain tissue). Unprovoked attacks and daytime attacks by nocturnal animals are considered highly suspect. A few cases of person-to-person transmission have been reported.[43]

Symptoms of rabies are nonspecific during the prodomal stage—fever, headache, malaise, irritability, nausea, and vomiting. The acute neurologic phase is characterized by hyperexcitability, hyperactivity, hallucinations, salivation, a fear of water and air. A minority of patients present with limp paralysis. Patients die within 5 days of presentation with these neurologic symptoms.

Human diploid cell vaccine (HDCV), and purified chick embryo cell (PCECV) rabies vaccine are killed vaccines used for preexposure and postexposure rabies virus prophylaxis. Preexposure

indications for using HDCV, RVA, or PCECV rabies vaccine include persons whose vocation or avocation place them at high risk for rabies exposure, such as veterinarians, animal handlers, laboratory workers in rabies research or diagnostic laboratories, cavers, wildlife officers where animal rabies is common, and anyone who handles bats. Travelers who will be in a country or area of a country where there is a constant threat of rabies, whose stay is likely to extend beyond 1 month, and who may not have readily available medical services (e.g., Peace Corps workers and missionaries) should be considered for preexposure prophylaxis.[43] Rabies immunization of immunocompromised individuals should be postponed until the immunosuppression has resolved, or activities should be modified to minimize the potential exposure to rabies. If the vaccine is used in immunocompromised persons, antibody titers should be checked postimmunization. Pregnancy is not a contraindication if the risk of rabies is great. A rabies immunization series should be completed with the same product because no data exist on interchangeability of products. Both vaccine preparations can be administered for preexposure prophylaxis as a three-dose series of 1 mL IM on days 0 and 7 and once between days 21 and 28.

Individuals with ongoing risk of exposure—either continuous risk (e.g., research laboratory staff or those involved in rabies biologics production) or individuals with frequent exposures (e.g., those involved with rabies diagnosis, spelunkers, veterinarians, animal control workers, and wildlife workers in rabies-enzootic areas)—should undergo serologic testing every 6 months and 2 years, respectively, to monitor rabies antibody concentrations. A booster dose is recommended if the complete virus neutralization is <1:5 serum dilution by the rapid fluorescent focus inhibition test.

Preexposure prophylaxis does not eliminate the need for postexposure therapy. Persons previously immunized with HDCV or PCECV rabies vaccine or those who previously received postexposure prophylaxis should receive two 1-mL IM doses of HDCV or PCECV rabies vaccine on postexposure days 0 and 3. Rabies Ig should not be given to this group.

Postexposure prophylaxis should be given after percutaneous or permucosal exposure to saliva or other infectious material from a high-risk source. Each case must be considered individually. Consideration needs to be given to the geographic area, species of animal, circumstances of the incident, and type of exposure. Local or state health departments should be contacted for assistance. Thorough cleansing of the wound with soap and water followed by irrigation with a virucidal agent such as povidone–iodine solution is an extremely important part of the management of rabies-prone wounds. Individuals who have not been immunized previously should receive the recommended regimen of rabies Ig (see Rabies Immunoglobulin below) and four doses of HDCV or PCECV rabies vaccine 1 mL IM on days 0, 3, 7, and 14 after exposure. However, a fifth dose in a series should be considered if the exposed individual is immunocompromised. Vaccine response for these individuals should be checked.[44] Rabies vaccine must be administered in the deltoid muscle in adults and in the anterolateral thigh in children. The gluteal region should not be used.[1,43]

Adverse reactions to rabies biologicals are less common and less serious with the currently available vaccines compared with previously used preparations. Local or mild systemic symptoms can typically be managed with antiinflammatory medications or antihistamines. Systemic allergic reactions ranging from hives to anaphylaxis occur in a very small number of subjects. Given the lack of alternative therapy and the fact that rabies infection is almost always fatal, persons exposed to rabies who do have adverse reactions should continue the vaccine series in a setting with medical support services.[43]

Rabies Immunoglobulin

Human rabies Ig is used in conjunction with rabies vaccine as part of postexposure rabies management for previously unvaccinated individuals. The product is derived from plasma obtained from donors who have been hyperimmunized with rabies vaccine and have high titers of circulating antibody.

In persons who previously have not been immunized against rabies, rabies Ig is given simultaneously with HDCV or PCECV rabies vaccine to provide optimal coverage in the interval before immune response to the vaccine occurs. The efficacy of this regimen has been clearly demonstrated. In situations where a vaccine has been used alone, mortality rates of 50% to 60% have been observed. Mortality after the combination vaccine and rabies Ig regimens is exceedingly rare; however, deaths have been reported when the wound was not infiltrated with rabies Ig.[45]

Rabies Ig does not interfere with vaccine-induced antibody formation. Its use is not recommended beyond 8 days after initiation of the vaccine series nor in persons previously immunized to rabies.

Human rabies Ig is administered in a dose of 20 international units/kg (0.133 mL/kg). If anatomically feasible, the entire dose should be infiltrated around the wound(s). Any remaining volume should be administered IM at a site distant from the rabies vaccination site. This product should never be administered by the intravenous route. Because other antibodies in the rabies Ig may interfere with the response to live-virus vaccines (MMR and varicella), it is recommended that these immunizations be delayed for 3 months.[1]

Side effects are rare but may include local soreness at the wound or IM injection site and mild temperature elevations. Caution is advised when administering the product to persons with known systemic allergies to immunoglobulin or thimerosal. Pregnancy is not a contraindication to its use.

RUBELLA VACCINE

Rubella (German measles) is characterized by an erythematous rash, lymphadenopathy, arthralgia, and low-grade fever. As many as 20% to 50% of rubella infections are asymptomatic.[25] The most important consequence of rubella infection occurs during pregnancy, particularly during the first trimester. Congenital rubella syndrome is associated with auditory, ophthalmic, cardiac, and neurologic defects. Rubella infection during pregnancy also can result in miscarriage or stillbirth. The primary goal of rubella immunization is to prevent congenital rubella syndrome. Rubella is no longer endemic in the United States, but high immunization rates are necessary to prevent rubella outbreaks from imported cases.

Rubella vaccine contains lyophilized live-attenuated rubella virus grown in human diploid cell culture. The vaccine is available in combination with measles vaccine, mumps vaccine, and varicella vaccine. Each 0.5-mL dose also contains 25 mcg neomycin and is administered subcutaneously.

Rubella vaccine induces antibodies that are protective against wild-virus infection. The duration of immunity has not been established. A second dose is recommended, however, at the same time measles vaccine is administered (as a second dose of MMR). The vaccine is indicated for children older than 1 year of age. Individuals born before 1957 are assumed to be immune to rubella except for women who could become pregnant. Therefore, all women of childbearing potential should have documentation of receiving at least one dose of a rubella-containing vaccine or laboratory evidence of immunity.[25] Recent administration of Ig interferes with rubella vaccine response for at least 3 months and depends on the dose of Ig that is administered.[1,25,46] Table 133–1 can be used as a guide for the recommended interval. The vaccine

should not be given to immunosuppressed individuals, although MMR vaccine should be administered to young children with HIV infection without severe immunosuppression as soon as possible after their first birthday.[26] The vaccine should not be given to individuals who have experienced anaphylactic reactions to neomycin.

Adverse effects of the rubella virus vaccine tend to increase with the age of the recipient. Mild symptoms are similar to wild-virus infection and include lymphadenopathy, rash, urticaria, fever, malaise, sore throat, headache, myalgias, and paresthesias of the extremities. These symptoms occur 7 to 12 days after vaccination and last 1 to 5 days. Joint symptoms occur more often in susceptible postpubertal females. Arthralgia occurs in 25% of vaccinees, and 10% have arthritis-like symptoms. These symptoms usually begin 1 to 3 weeks after vaccination and persist for 1 day to 3 weeks. A very small excess risk of chronic arthropathy exists.[25] The vaccine may cause suppression of tuberculin skin tests for up to 6 weeks after vaccination. The vaccine virus may be excreted in nose and throat secretions, but it is not contagious.

The rubella vaccine has never been associated with congenital rubella syndrome, but its use during pregnancy is contraindicated. However, routine pregnancy testing prior to vaccination is not recommended. Women should be counseled not to become pregnant for 4 weeks following vaccination.[46] Termination of pregnancy is not indicated in women who are accidentally given the vaccine or who become pregnant during the month after vaccination.

VARICELLA AND ZOSTER VACCINES

Varicella is a highly contagious disease caused by varicella-zoster virus. The clinical illness is characterized by the appearance of successive waves of pruritic vesicles that rapidly crust over. Malaise and fever are common and last for 2 to 3 days. The virus remains dormant in the dorsal ganglia and reactivates as herpes zoster, also known as *shingles*. Although the exact stimulus for reactivation is unknown, a decrease in varicella-specific cell-mediated immunity associated with age or immunosuppression appears to be necessary but not sufficient for reactivation.

Varicella Vaccine

Live-attenuated varicella vaccine contains the Oka/Merck strain of varicella virus, which was attenuated by propagation through several different cell culture lines. Varicella vaccine is a lyophilized product that must be kept frozen and protected from light. Once reconstituted, it must be administered subcutaneously within 30 minutes. Each 0.5-mL dose contains a minimum of 1,350 plaque-forming units of virus as well as 12.5 mg of hydrolyzed gelatin and trace amounts of neomycin, fetal bovine serum, and residual components from cell culture.[47]

The varicella vaccine is safe and immunogenic in healthy children and adults. In clinical studies, varicella vaccine has been 70% to more than 95% effective in preventing chickenpox. Vaccinated individuals who develop chickenpox typically experience milder disease, with low or no fever and fewer skin lesions, many of which do not vesiculate. Similarly, vaccinated individuals who develop breakthrough infections transmit the varicella virus to others at a lower rate.[14]

The varicella vaccine is recommended for all children at 12 to 18 months of age, with a second dose prior to entering school between ages 4 and 6 years.[16] A second dose is also recommended for patients older than this age if they have not already had chickenpox. Varicella vaccine can be used for postexposure prophylaxis. The vaccine is effective in the prevention or modification of varicella infection when given within 3 days and possibly 5 days of exposure. Because the varicella vaccine is a live vaccine, it is contraindicated in pregnant women and in immunocompromised individuals. An exception is children with asymptomatic or mildly symptomatic HIV infection, who should receive two doses of varicella vaccine 3 months apart. Also, children with humoral immune deficiencies may be immunized. Varicella vaccination is contraindicated in individuals with a history of anaphylactic reaction to any component of the vaccine. Persons who have received blood, plasma, or Ig products in the recent past should not receive varicella vaccine because of concern that passively acquired antibody will interfere with response to the vaccine. The recommended time interval between antibody-containing products and varicella vaccine depends on the dose of immunoglobulin (see Table 133–1). Although no adverse events associated with salicylate use after vaccination have been reported, salicylates should be avoided for 6 weeks after vaccination because of the association of salicylate use and Reye syndrome following varicella infection.[47]

The varicella vaccine has an excellent safety record. Pain, local swelling, and erythema at the injection site occur in up to 32% of patients and fever in 10% to 15%. A varicella-like rash occurs in approximately 4% of vaccinees, accompanied by few, if any, systemic symptoms. The rash may be localized at the injection site or generalized. Lesions usually are few in number (2–10) and often papular rather than vesicular. Transmission of vaccine virus to susceptible close contacts has occurred but is rare and believed to occur only when the vaccinee develops a rash. Because the risk of vaccine virus transmission is very low and primary infection can be very severe, vaccination of household contacts of immunocompromised patients is recommended to prevent introduction of varicella into the household.[47]

Zoster Vaccine

After the primary infection with varicella-zoster virus manifested as chicken pox, the virus remains latent in the dorsal ganglia. Herpes zoster, more commonly known as *shingles*, occurs upon reactivation of varicella-zoster virus replication. Herpes zoster can occur at any age, but the incidence dramatically increases with increasing age. The rate of disease increases sharply beginning in the after age 50 years. The disease rate in individuals older than 80 years of age is 11 cases per 1,000 person-years.[48] Patients with HIV, cancer, or other conditions associated with immunosuppression are at increased risk for disease.[10] The development of the disease is associated with declining cellular immunity to varicella-zoster virus.

The clinical presentation of herpes zoster usually is a vesicular eruption limited to one dermatome. The most common complication is postherpetic neuralgia, which is pain that persists after the skin lesions have healed. The duration and severity of the pain varies. Postherpetic neuralgia can persist for weeks to years. The risk of postherpetic neuralgia increases dramatically with age. Virtually no risk of developing postherpetic neuralgia with herpes zoster exists prior to age 50 years, but the risk increases to 50% to 75% after ages 60 and 75 years, respectively. The pain can be so severe as to limit activities of daily living and quality of life.[10]

The zoster vaccine contains 19,000 plaque-forming units of Oka/Merck strain live varicella-zoster virus. Although the same strain of vaccine virus is contained in the childhood varicella vaccines, the doses of vaccine virus are dramatically different, and the vaccines are *not* interchangeable. Zoster vaccine reduces the burden of disease by 60%. The burden of disease is a composite measure considering incidence, severity, and duration of herpes zoster. The incidence of zoster is cut in half and the development of postherpetic neuralgia can be decreased by 67%.[49]

The zoster vaccine is recommended for immunocompetent individuals older than 60 years. This live vaccine should not be used in immunocompromised individuals, including those on high dose

TABLE 133-4 Zoster Vaccine Use in Special Populations[10]

- Immunize patients with a history of shingles
- Screening patients for a history of chickenpox is not necessary. Assume anyone born before 1980 is immune to varicella[47]
- Zoster vaccine may be administered to individuals on inhaled, topical or intra-articular steroids or low dose oral steroids
- Zoster vaccine may be administered to individuals treated with low-dose methotrexate (<0.4 mg/kg/wk) or 6-mercaptopurine (<1.5 mg/kg/day). These therapies are often used for autoimmune diseases
- The vaccine may be administered to individuals anticipating immunosuppressive therapy. The minimum duration between immunization and initiation of immunosuppressive therapy is 14 days, and some clinicians recommend 1 month
- Stop antiviral therapy at least 24 hours before immunization and restart it at least 14 days after immunization
- Zoster vaccine can be administered without regard to blood product or immunoglobulin administration
- Do not administer zoster vaccine to
  - Individuals with AIDS or clinical manifestations of HIV, such as a $CD4^+$ count less than 200 per mm^3
  - Patients on high doses of steroids (prednisone or its equivalent of 20 mg daily or more for more than 2 weeks)
- Risks and benefits of administering zoster vaccine to individuals on immune modulators, such as tumor necrosis factor agents, must be determined on a case-by-case basis. Immunize prior to initiating therapy if possible. A recent study observed a rate of 11 cases per 1000 person-years which is similar to the zoster rate in people older than 80 years of age[59,60]

corticosteroids or with HIV (CD4 cell count <200/mm^3) or malignancies.[10] Immunization of some special populations can be done (see Table 133–4). No evidence of transmission of the live vaccine virus exists, but transmission of the varicella vaccine virus has been documented. Postmarketing surveillance will be used to establish if the theoretical risk is a small clinical problem. The duration of protection is unknown but immunized participants from clinical trials are being followed for immunological markers and clinical efficacy.[49] Future doses may be required for continued protection.

Varicella-Zoster Immunoglobulin

Varicella-zoster Ig is used after exposure to varicella for passive immunization of susceptible immunodeficient patients or other susceptible individuals at particularly high risk for complications of varicella infection. Varicella-zoster Ig is available only under an investigational new drug protocol.[50]

Postexposure prophylaxis with varicella-zoster Ig is indicated for the following susceptible individuals: (a) immunocompromised patients, (b) neonates whose mothers develop varicella within 5 days before or 2 days after delivery, (c) preterm infants (<28 weeks' gestation or weight <1,000 g) who are exposed to varicella while hospitalized, and (d) susceptible pregnant women.[50] If varicella is prevented, vaccination should be offered at a later date. Exposure to varicella is defined as direct indoor contact for more than 1 hour with an infectious person. A negative history of clinical disease is not a reliable indicator of varicella susceptibility. Most people with a negative clinical history will have detectable antibody on laboratory testing. Caution is warranted when interpreting a low positive result in an immunosuppressed patient who has received blood products or Ig because the circulating antibody may be acquired passively.

For maximum effectiveness, varicella-zoster Ig must be given as soon as possible and not more than 96 hours following exposure. Because this agent may only attenuate infection, patients who receive varicella-zoster Ig still may have a period of communicability, and varicella-zoster Ig may prolong the incubation period to 28 days. Antiviral therapy can be initiated if signs and symptoms of varicella infection become apparent.

Administration of varicella-zoster Ig is by the IM route at doses of 125 plaque-forming units per 10 kg of body weight up to 625 units (five vials) for patients weighing more than 40 kg. The dose for newborn infants is 125 units.

OTHER IMMUNOBIOLOGICS

IMMUNOGLOBULIN

Immunoglobulin is available as both an intramuscular (IMIG) and an intravenous (IVIG) preparation. The IMIG preparation, or the Cohn fraction II, is prepared from pooled plasma of several thousand donors by cold ethanol fractionation. It typically contains greater than 95% IgG and trace amounts of IgM, IgA, and other plasma proteins. Because Ig is harvested from a large donor pool, it contains a wide spectrum of IgG antibodies to the pathogens prevalent in the area from which the donors were obtained. In the fractionation process, high-molecular-weight IgG aggregates are formed, which can activate complement in the absence of antigen and precipitate anaphylactoid reactions. For this reason, IMIG is unsuitable for IV administration. IMIG typically contains 15% to 18% protein and not less than 90% IgG. A number of IVIG preparations are available commercially in the United States. Generally, these preparations contain greater than 90% IgG monomers and trace to small amounts of IgA. These products are available as lyophilized powders or solutions.

When administered either IV or IM, Ig distributes in approximately 5% of the body weight of the recipient. The plasma half-life of Ig ranges from 18 to 32 days. This range of half-life probably is attributable to the variation in the half-life of IgG subclasses. Peak serum concentrations occur immediately with IVIG but within 2 days with IMIG. After the initial period of equilibration, circulating IgG levels are superimposable between IV and IM equivalent dosages. No dosage adjustment is necessary in patients with renal insufficiency, hepatic insufficiency, or both, dialysis patients, or geriatric patients.

8 Immunoglobulin is indicated in a wide variety of circumstances to provide passive immunity to individuals. The indications for IMIG differ from those for IVIG. IMIG is indicated for providing passive immunity in patients with hepatitis A infections in those <1 year and older than 39 years, hepatitis B exposures (however, hepatitis B Ig is significantly more effective), measles, varicella, and primary immunodeficiency diseases. Although IMIG is indicated for treatment of primary immunodeficiency, IVIG is better tolerated and is more effective. IMIG is not indicated for prevention of rubella, mumps, or poliomyelitis. Table 133–5 lists the suggested dosages of IMIG for prevention or attenuation of various infectious diseases.

There are many licensed indications, as well as off-label uses, for IVIG.[51] The therapeutic dose of IVIG is set empirically at 2 g/kg,[52] often given as five daily doses of 400 mg/kg each. However, it may be preferable to divide the total dose into two daily doses of 1 g/kg if the patient can tolerate the volume of the infusion. Mechanisms of IVIG action for treatment of these conditions have been hypothesized.

- *Primary Immunodeficiency States.*[53] In primary immunodeficiency states, monthly doses of between 100 and 800 mg/kg are administered; the average dose is 200 to 400 mg/kg. The immunodeficiency states for which IVIG is indicated include both antibody deficiencies and combined immune deficiencies. Significant reactions can occur in patients with low intrinsic levels of IgA given IVIG with greater amounts of IgA. An IVIG product with very low amounts of IgA should be used for these patients.

TABLE 133-5 Indications and Dosage of Intramuscular Immunoglobulin in Infectious Diseases

Primary immunodeficiency states	1.2 mL/kg IM then 0.6 mL/kg every 2–4 weeks
Hepatitis A exposure	0.02 mL/kg IM within 2 weeks if <1 year or >39 years of age
Hepatitis A prophylaxis	0.02 mL/kg IM for exposure <3 months' duration 0.06 mL/kg IM for exposure up to 5 months' duration
Hepatitis B exposure	0.06 mL/kg (HBIG preferred in known exposures)
Measles exposure	0.25 mL/kg (maximum dose 15 mL) as soon as possible 0.5 mL/kg (maximum dose 15 mL) as soon as possible for immunocompromised individuals
Varicella exposure	0.6–1.2 mL/kg as soon as possible when VZIG not available

- *Idiopathic (Immune) Thrombocytopenic Purpura.*[54] For treatment of hemorrhage associated with idiopathic (immune) thrombocytopenic purpura (ITP), doses of 1 g/kg daily for 2 to 3 days plus high-dose methylprednisolone are indicated. Adults tend to respond less well to IVIG than do children. IVIG is acceptable for treatment of both chronic and acute ITP, and IVIG has been used for ITP associated with pregnancy without adverse effects on the fetus. Corticosteroids remain the drugs of choice for adult ITP. In thrombotic thrombocytopenia purpura, IVIG is reported to be effective in patients who do not respond to plasmapheresis. Other platelet disorders in which IVIG may be useful include neonatal immune thrombocytopenia, perinatal autoimmune thrombocytopenia, drug-induced thrombocytopenia, thrombocytopenia secondary to infection, and transfusion-refractory thrombocytopenia; however, the data supporting these uses are minimal.
- *Chronic Lymphocytic Leukemia.* IVIG is used as a prophylactic measure in patients with chronic lymphocytic leukemia who have had a serious bacterial infection. Doses of 400 mg/kg every 3 to 4 weeks are used.
- *Kawasaki's Disease (Mucocutaneous Lymph Node Syndrome).* This disease, which generally occurs in children, carries the hallmark of development of coronary artery abnormalities. Generally, the American Academy of Pediatrics recommends that if the strict criteria for Kawasaki's disease are met, an IVIG dose of 400 mg/kg/day for 4 consecutive days be used or, preferably, 2 g/kg as a single dose. The dose should be administered within 10 days of disease onset. Aspirin therapy also should be initiated.[55]
- *Varicella-Zoster.* Another licensed indication for IVIG is for prophylaxis of varicella-zoster if varicella-zoster Ig is not available.

A number of other proposed uses of IVIG have been identified. It is important to note that these uses are off-label but may be generally accepted in the medical community for routine treatment.[51,52,56] Off-label uses include the following:

- *Neonatal Sepsis.* Neonatal sepsis can cause significant morbidity within 24 hours of birth. Group B *Streptococcus* and *Escherichia coli* are the primary infecting organisms, but other bacteria and fungi may be associated with sepsis. IVIG appears to be effective in neonates older than 34 weeks' gestational age or who weigh less than 1,500 g. Routine use is not recommended; however, IVIG may be useful in neonates with recurrent infections.
- *Guillain-Barré Syndrome.* IVIG is effective and is considered an alternative to plasmapheresis.[56]
- *Autoimmune Diseases.* IVIG may be effective in self-limited immunoregulatory diseases but less effective in chronic diseases such as systemic lupus erythematosus. Overall, little evidence indicates that IVIG is useful for management of autoimmune diseases, except for patients with severe active disease who have not responded to or tolerated other interventions.[56]
- *Intractable Epilepsy.* IVIG may be useful for patients with confirmed IgG deficiency. IVIG may be considered for certain syndromes, such as West or Lennox-Gastaut's syndrome.[56]
- *Chronic Inflammatory Demyelinating Polyneuropathy.* Although steroids are the first-line therapy, IVIG may be used in patients who do not respond to or do not tolerate steroids.[56]

Adverse effects of Ig vary with the route of administration. Following IMIG, pain, tenderness, and muscle stiffness persisting for hours or days are common. Repeat courses may cause sensitization with resulting allergic reactions. 9 With IVIG, adverse effects occur in fewer than 1% of immunocompetent patients and in fewer than 10% of other patients. Chills, fever, nausea, and vomiting often are related to the rate of the infusion. Infusion should be given at a rate of 0.01 to 0.02 mL/kg/min for 30 minutes. If no reactions occur, then the rate can be increased to 0.02 to 0.04 mL/kg/min. If reactions do occur, the infusion should be stopped for 30 minutes and restarted at a lower rate. Although recommendations for infusion rate vary slightly depending on the preparation, the guidelines presented can be followed for the various IV preparations.

Most adverse reactions are mild and transient. Arthralgia, myalgia, fever, pruritus, nausea, vomiting, chest tightness, palpitations, diaphoresis, dizziness, pallor, and respiratory distress have been reported. Rarely, aseptic meningitis has occurred from a few hours to 2 days after high-dose infusion. The syndrome resolves within days without sequelae. Acute renal failure has been reported, primarily in individuals with underlying renal dysfunction, diabetes, sepsis, volume depletion, or other nephrotoxic drugs or in patients older than 65 years. To minimize the risk, ensure adequate hydration prior to infusion and choose an IVIG product that does not contain high sucrose concentrations for individuals at high risk.[57,58]

Immunoglobulin products are derived from human blood. Precautions such as donor screening and fractionation procedures and solvent-detergent treatment during the manufacturing process render the IVIG products free of HIV and hepatitis B and C viruses. Although no manufacturing process can guarantee no viral contamination, the potential infection risk from Ig preparations is very small.[57]

$RH_o(D)$ IMMUNOGLOBULIN

Second only to the ABO blood group system, Rhesus antigen D [$Rh_o(D)$] is an important antigen in human blood. The $Rh_o(D)$ locus encodes this antigen, but this locus is absent in approximately 15% of the population. 10 Individuals lacking the $Rh_o(D)$ locus are $Rh_o(D)$ negative and have the potential to mount an antibody response to erythrocytes with the $Rh_o(D)$ present. $Rh_o(D)$ incompatibility during pregnancy can lead to sensitization of the mother. The maternal antibodies developed following normal fetal leakage of erythrocytes to the mother can cause hemolytic disease of the newborn during subsequent pregnancies.

Rh_o(D) Ig is a sterile solution of immunoglobulins prepared from human sera with high titers of Rh_o(D) antibody. Rh_o(D) Ig suppresses the antibody response and formation of anti-Rh_o(D) in Rh_o(D)-negative women exposed to Rh_o(D)-positive blood. Administration of Rh_o(D) Ig prevents hemolytic disease of the newborn in subsequent pregnancies with a Rh_o(D)-positive fetus. When administered within 72 hours of delivery of a full-term infant, Rh_o(D) Ig reduces active antibody formation from 12% to 1% to 2%. The reduction in antibody formation is lower when Rh_o(D) Ig is given beyond 72 hours postpartum. Smaller doses of Rh_o(D) Ig are used after abortion, miscarriage, amniocentesis, or abdominal trauma. In addition, Rh_o(D) Ig is used in the case of a premenopausal woman who is Rh_o(D) negative and has inadvertently received Rh_o(D)-positive blood or blood products.

The dosage of Rh_o(D) Ig varies with the indication. A standard dose of 300 mcg is given within 72 hours of a term delivery. Occasionally, when the fetus is known to be Rh_o(D) positive, a 300-mcg dose is given at 28 weeks' gestation and within 72 hours after delivery. For postpregnancy termination occurring up to 13 weeks' gestation, one microdose (50 mcg) vial is given within 72 hours. For pregnancy termination after 13 weeks, one standard dose (300 mcg) is given within 72 hours. In other circumstances, such as in abdominal trauma, amniocentesis, or transfusion accidents, the dosage (number of standard dose vials) is based on the estimated packed red blood cell volume of fetal/maternal hemorrhage divided by 15. Rh_o(D) Ig is administered IM only.

When considering use of Rh_o(D) Ig use, the mother's Rh_o(D) antigen status must be known with certainty. Rh_o(D) Ig should not be given to individuals positive for this antigen or to those with anti-Rh_o(D) antibodies. Occasionally, a large fetal bleed of Rh_o(D)-positive blood may make cross-matching of the mother difficult. In these cases, Rh_o(D) Ig should be given only if previous tests have shown that the mother is Rh_o(D) negative with no anti-Rh_o(D) antibody.

Adverse reactions to Rh_o(D) Ig include injection-site tenderness and fever. Rh_o(D) does not interfere with response to rubella vaccine. Rubella-seronegative women should be immunized at hospital discharge even if they received Rh_o(D) Ig postpartum.

CYTOMEGALOVIRUS IMMUNOGLOBULIN

Cytomegalovirus (CMV) causes a generally mild infection in immunocompetent individuals. However, immunocompromised individuals are at risk for serious complications, including pneumonia, retinitis, gastrointestinal manifestations, and hepatitis. CMV causes a latent infection that can be transmitted from a previously infected solid organ donor to a seronegative recipient. CMV-IVIG contains IgG antibodies obtained from healthy persons with high titers of antibodies to CMV.

Attenuation of primary CMV disease associated with solid-organ transplantation in seronegative recipients of seropositive organs is the indication for CMV-IVIG. It is dosed using a tapering schedule that varies depending on the type of transplant. CMV-IVIG is administered intravenously every 2 weeks, with the final dose administered 16 weeks post-transplantation. Use of CMV-IVIG has resulted in a significant decrease in CMV-related syndromes.

Adverse effects of CMV-IVIG are seen in fewer than 5% of recipients and include flushing, chills, muscle cramps, back pain, chest tightness, fever, nausea, vomiting, hypotension, and tachycardia. These adverse events may be related to the infusion rate and can be managed by temporarily discontinuing the infusion. The infusion can be restarted at a decreased rate. Anaphylaxis occurs rarely and should be considered if hypotension develops during the infusion. Because CMV-IVIG contains other antibodies, live-virus vaccines should be withheld until 3 months after CMV-IVIG administration.

VACCINE INFORMATION RESOURCES

The field of vaccinology is developing ever more rapidly, with numerous changes in recommendations for vaccine use made each year. Keeping up to date with the current recommendations can be a challenge. The childhood, adolescent, and adult immunization schedules are updated frequently and published annually. Recommendations for the use of influenza vaccine are issued annually. Healthcare providers involved in primary care and immunization delivery must keep themselves abreast of these changes in a systematic way. Reading electronic newsletters and browsing reliable Websites are efficient methods for obtaining information (Table 133–6). Although several excellent, reliable, and timely Websites exist, hundreds of sites with misleading and incorrect information also exist. Many of these sites are targeted at parents.

Vaccines are the only class of medications to which nearly every patient is exposed. Knowledge of these agents is critical to providing pharmaceutical care. Dramatic progress in public health has been made through the appropriate use of immunization. Additional improvements in quality of life and mortality can be made through continued increases in vaccination coverage with careful attention to this aspect of care by all healthcare providers.

ABBREVIATIONS

ACIP: Advisory Committee on Immunization Practices
CDC: U.S. Centers for Disease Control and Prevention
CMV-IVIG: Cytomegalovirus intravenous immunoglobulin
DTaP: diphtheria-tetanus-acellular pertussis
HDCV: human diploid cell rabies vaccine
Hib: *Haemophilus influenzae* type b
HPV: human papilloma virus
Ig: immunoglobulin
IMIG: intramuscular immunoglobulin
IPV: inactivated polio vaccine
ITP: idiopathic (immune) thrombocytopenic purpura
IVIG: intravenous immunoglobulin
MMRV: measles-mumps-rubella vaccine
OPV: oral polio vaccine
PCECV: purified chick embryo cell rabies vaccine
PCV: pneumococcal conjugate vaccine

PPSV23: pneumococcal polysaccharide vaccine 23 valent

PRP: polyribosylribitol phosphate

Td: tetanus-diphtheria

Tdap: tetanus-diphtheria-acellular pertussis

VAERS: Vaccine Adverse Event Reporting System

Appendix 133-1

2010 Childhood and Adolescent Immunization Schedules

Recommended Immunization Schedule for Persons Aged 0 Through 6 Years—United States • 2010

For those who fall behind or start late, see the catch-up schedule

Vaccine ▼ / Age ▶	Birth	1 Month	2 Month	4 Month	6 Month	12 Month	15 Month	18 Month	19–23 Month	2–3 Years	4–6 Years
Hepatitis B[1]	HepB	HepB			HepB						
Rotavirus[2]			RV	RV	RV[2]						
Diphtheria, tetanus, pertussis[3]			DTaP	DTaP	DTaP	*See footnote*[3]	DTaP				DTaP
Haemophilus influenzae type b[4]			Hib	Hib	Hib[4]	Hib					
Pneumococcal[5]			PCV	PCV	PCV	PCV				PPSV	
Inactivated poliovirus[6]			IPV	IPV	IPV						IPV
Influenza[7]					Influenza (yearly)						
Measles, mumps, rubella[8]						MMR		*See footnote*[8]			MMR
Varicella[9]						Varicella		*See footnote*[9]			Varicella
Hepatitis A[10]						HepA (2 doses)				HepA series	
Meningococcal[11]										MCV	

Range of recommended ages for all children except certain high-risk groups

Range of recommended ages for certain high-risk groups

This schedule includes recommendations in effect as of December 15, 2009. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Considerations should include provider assessment, patient preference, and the potential for adverse events. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations: **http://www.cdc.gov/vaccines/pubs/acip-list.htm**. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS) at **http://www.vaers.hhs.gov** or by telephone, **800-822-7967**.

1. **Hepatitis B vaccine (HepB).** (Minimum age: birth)
   At birth:
   - Administer monovalent HepB to all newborns before hospital discharge.
   - If mother is hepatitis B surface antigen (HBsAg)-positive, administer HepB of hepatitis B immune globulin (HBIG) within 12 hours of birth.
   - If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if HBsAg-positive, administer HBIG (no later than age 1 week).

   After the birth dose:
   - The HepB series should be completed with either monovalent HepB or a combination vaccine containing HepB. The second dose should be administered at age 1 or 2 months. Monovalent HepB vaccine should be used for doses administered before age 6 weeks. The final dose should be administered no earlier than age 24 weeks.
   - Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg 1 to 2 months after completion of at least 3 doses of the HepB series, at age 9 through 18 months (generally at the next well-child visit).
   - Administration of 4 doses of HepB to infants is permissible when a combination vaccine containing HepB is administered after the birth dose. The fourth dose should be administered no earlier than age 24 weeks.
2. **Rotavirus vaccine (RV).** (Minimum age: 6 weeks)
   - Administer the first dose at age 6 through 14 weeks (maximum age: 14 weeks 6 days). Vaccination should not be initiated for infants aged 15 weeks 0 days or older.
   - The maximum age for the final dose in the series is 8 months 0 days.
   - If Rotarix is administered at ages 2 and 4 months, a dose at 6 months is not indicated.
3. **Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).** (Minimum age: 6 weeks)
   - The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
   - Administer the final dose in the series at age 4 through 6 years.
4. ***Haemophilus influenzae* type b conjugate vaccine (Hib).** (Minimum age: 6 weeks)
   - If PRP-OMP (PedvaxHIB or Comvax [HepB-Hib]) is administered at ages 2 and 4 months, a dose at age 6 months is not indicated.
   - TriHiBit (DTaP/Hib) and Hiberix (PRP-T) should not be used for doses at ages 2, 4, or 6 months for the primary series but can be used as the final dose in children aged 12 months through 4 years.
5. **Pneumococcal vaccine.** (Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPSV])
   - PCV is recommended for all children aged younger than 5 years. Administer 1 dose of PCV to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
   - Administer PPSV 2 or more months after last dose of PCV to children aged 2 years or older with certain underlying medical conditions, including a cochlear implant. See *MMWR* 1997;46(No. RR-8).
6. **Inactivated poliovirus vaccine (IPV)** (Minimum age: 6 weeks)
   - The final dose in the series should be administered on or after the fourth birthday and at least 6 months following the previous dose.
   - If 4 doses are administered prior to age 4 years a fifth dose should be administered at age 4 through 6 years. See *MMWR* 2009;58(30):829–30.
7. **Influenza vaccine (seasonal).** (Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 2 years for live, attenuated influenza vaccine [LAIV])
   - Administer annually to children aged 6 months through 18 years.
   - For healthy children aged 2 through 6 years (i.e., those who do not have underlying medical conditions that predispose them to influenza complications), either LAIV or TIV may be used, except LAIV should not be given to children aged 2 through 4 years who have had wheezing in the past 12 months.
   - Children receiving TIV should receive 0.25 mL if aged 6 through 35 months or 0.5 mL if aged 3 years or older.
   - Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.
   - For recommendations for use of influenza A (H1N1) 2009 monovalent vaccine see *MMWR* 2009;58(No. RR-10).
8. **Measles, mumps, and rubella vaccine (MMR).** (Minimum age: 12 months)
   - Administer the second dose routinely at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.
9. **Varicella vaccine.** (Minimum age: 12 months)
   - Administer the second dose routinely at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
   - For children aged 12 months through 12 years the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
10. **Hepatitis A vaccine (HepA).** (Minimum age: 12 months)
    - Administer to all children aged 1 year (i.e., aged 12 through 23 months). Administer 2 doses at least 6 months apart.
    - Children not fully vaccinated by age 2 years can be vaccinated at subsequent visits.
    - HepA also is recommended for older children who live in areas where vaccination programs target older children, who are at increased risk for infection, or for whom immunity against hepatitis A is desired.
11. **Meningococcal vaccine.** (Minimum age: 2 years for meningococcal conjugate vaccine [MCV4] and for meningococcal polysaccharide vaccine [MPSV4])
    - Administer MCV4 to children aged 2 through 10 years with persistent complement component deficiency, anatomic or functional asplenia, and certain other conditions placing them at high risk.
    - Administer MCV4 to children previously vaccinated with MCV4 or MPSV4 after 3 years if first dose administered at age 2 through 6 years. See *MMWR* 2009; 58:1042–3.

The Recommended Immunization Schedules for Persons Aged 0 through 18 Years are approved by the Advisory Committee on Immunization Practices (**http://www.cdc.gov/vaccines/recs/acip**), the American Academy of Pediatrics (**http://www.aap.org**), and the American Academy of Family Physicians (**http://www.aafp.org**).

CS207330-A

Recommended immunization schedule for persons aged 7 through 18 years — United States • 2010

For those who fall behind or start late, see the schedule below and the catch-up schedule

Vaccine ▼ / Age ▶	7–10 years	11–12 years	13–18 years
Tetanus, diphtheria, pertussis[1]		Tdap	Tdap
Human papillomavirus[2]	*see footnote 2*	HPV (3 doses)	HPV series
Meningococcal[3]	MCV	MCV	MCV
Influenza[4]	Influenza (yearly)		
Pneumococcal[5]	PPSV		
Hepatitis A[6]	Hep A series		
Hepatitis B[7]	Hep B series		
Inactivated poliovirus[8]	IPV series		
Measles, mumps, rubella[9]	MMR series		
Varicella[10]	Varicella series		

Range of recommended ages for all children except certain high-risk groups

Range of recommended ages for catch-up immunization

Range of recommended ages for certain high-risk groups

This schedule includes recommendations in effect as of December 15, 2009. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Considerations should include provider assessment, patient preference, and the potential for adverse events. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations: **http://www.cdc.gov/vaccines/pubs/acip-list.htm.** Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS) at **http://www.vaers.hhs.gov** or by telephone, **800-822-7967**.

1. Tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap). (Minimum age: 10 years for boostrix and 11 years for Adacel)
- Administer at age 11 or 12 years for those who have completed the recommended childhood DTP/DTaP vaccination series and have not received a tetanus and diphtheria toxoid (Td) booster dose.
- Persons aged 13 through 18 years who have not received Tdap should receive a dose.
- A 5-year interval from the last Td dose is encouraged when Tdap is used as a booster dose; however, a shorter interval may be used if pertussis immunity is needed.

2. Human papillomavirus vaccine (HPV). (Minimum age: 9 years)
- Two HPV vaccines are licensed: a quadrivalent vaccine (HPV4) for the prevention of cervical, vaginal and vulvar cancers (in females) and genital warts (in females and males), and a bivalent vaccine (HPV2) for the prevention of cervical cancers in females.
- HPV vaccines are most effective for both males and females when given before exposure to HPV through sexual contact.
- HPV4 or HPV2 is recommended for the prevention of cervical precancers and cancers in females.
- HPV4 is recommended for the prevention of cervical, vaginal and vulvar precancers and cancers and genital warts in females.
- Administer the first dose to females at age 11 or 12 years.
- Administer the second dose 1 to 2 months after the first dose and the third dose 6 months after the first dose (at least 24 weeks after the first dose).
- Administer the series to females at age 13 through 18 years if not previously vaccinated.
- HPV4 may be administered in a 3-dose series to males aged 9 through 18 years to reduce their likelihood of acquiring genital warts.

3. Meningococcal conjugate vaccine (MCV4).
- Administer at age 11 or 12 years, or at age 13 through 18 years if not previously vaccinated.
- Administer to previously unvaccinated college freshmen living in a dormitory.
- Administer MCV4 to children aged 2 through 10 years with persistent complement component deficiency, anatomic or functional asplenia, or certain other conditions placing them at high risk.
- Administer to children previously vaccinated with MCV4 or MPSV4 who remain at increased risk after 3 years (if first dose administered at age 2 through 6 years) or after 5 years (if first dose administered at age 7 years or older). Persons whose only risk factor is living in on-campus housing are not recommended to receive an additional dose. See *MMWR* 2009;58:1042–3.

4. Influenza vaccine (seasonal)
- Administer annually to children aged 6 months through 18 years.
- For healthy nonpregnant persons aged 7 through 18 years (i.e., those who do not have underlying medical conditions that predispose them to influenza complications), either LAIV or TIV may be used.
- Administer 2 doses (separated by at least 4 weeks) to children aged younger then 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.
- For recommendations for use of influenza A (H1N1) 2009 monovalent vaccine. See *MMWR* 2009;58(No. RR-10).

5. Pneumococcal polysaccharide vaccine (PPSV).
- Administer to children with certain underlying medical conditions, including a cochlear implant. A singlerevaccination should be administered after 5 years to children with functional or anatomic asplenia or an immunocompromising condition. See *MMWR* 1997;46(No. RR-8).

6. Hepatitis A vaccine (HepA).
- Administer 2 doses at least 6 months apart.
- HepA is recommended for children aged older than 23 months who live in areas where vaccination programs target older children, who are at increased risk for infection, or for whom immunity against hepatitis A is desired.

7. Hepatitis B vaccine (HepB).
- Administer the 3-dose series to those not previously vaccinated.
- A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB is licensed for children aged 11 through 15 years.

8. Inactivated poliovirus vaccine (IPV).
- The final dose in the series should be administered on or after the fourth birthday and at least 6 months following the previous dose.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

9. Measles, mumps, and rubella vaccine (MMR).
- If not previously vaccinated, administer 2 doses or the second dose for those who have received only 1 dose, with at least 28 days between doses.

10. Varicella vaccine.
- For persons aged 7 through 18 years without evidence of immunity (see *MMWR* 2007;56[No. RR-4]), administer 2 doses if not previously vaccinated or the second dose if only 1 dose has been administered.
- For persons aged 7 through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
- For persons aged 13 years and older, the minimum interval between doses is 28 days.

CS207330-A

The Recommended Immunization Schedules for Persons Aged 0 through 18 Years are approved by the Advisory Committee on Immunization Practices **(http://www.cdc.gov/vaccines/recs/acip)**, the American Academy of Pediatrics **(http://www.aap.org)**, and the American Academy of Family Physicians **(http://www.aafp.org).**
Department of Health and Human Services • Centers for Disease Control and Prevention

Catch-up Immunization Schedule for Persons Aged 4 Months Through 18 Years Who Start Late or Who Are More Than 1 Month Behind—United States • 2010

The table below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age.

Vaccine	Minimum age for dose 1	Minimum interval between doses: Dose 1 to dose 2	Dose 2 to dose 3	Dose 3 to dose 4	Dose 4 to dose 5
Persons aged 4 months through 6 years					
Hepatitis B[1]	Birth	**4 weeks**	**8 weeks** (and at least 16 weeks after first dose)		
Rotavirus[2]	6 wks	**4 weeks**	**4 weeks**[2]		
Diphtheria, tetanus, pertussis[3]	6 wks	**4 weeks**	**4 weeks**	**6 months**	**6 months**[3]
Haemophilus influenzae type b[4]	6 wks	**4 weeks** if first dose administered at younger than age 12 months **8 weeks (as final dose)** if first dose administered at age 12–14 months **No further doses needed** if first dose administered at age 15 months or older	**4 weeks**[4] if current age is younger than 12 months **8 weeks (as final dose)**[4] if current age is 12 months or older and first dose administered at younger than age 12 months and second dose administered at younger than 15 months **No further doses needed** if previous dose administered at age 15 months or older	**8 weeks (as final dose)** This dose only necessary for children aged 12 months through 59 months who received 3 doses before age 12 months	
Pneumococcal[5]	6 wks	**4 weeks** if first dose administered at younger than age 12 months **8 weeks (as final dose for healthy children)** if first dose administered at younger than age 12 months or current age 24 through 59 months **No further doses needed** if first dose administered at age 12–14 months administered at age 24 months or older	**4 weeks** if current age is younger than 12 months **8 weeks (as final dose for healthy children)** if current age is 12 months or older **No further doses needed** for healthy children if previous dose administered at age 24 months or older	**8 weeks (as final dose)** This dose only necessary for children aged 12 months through 59 months who received 3 doses before age 12 months or for high-risk children who received 3 doses at any age	
Inactivated poliovirus[6]	6 wks	**4 weeks**	**4 weeks**	**6 months**	
Measles, mumps, rubella[7]	12 mos	**4 weeks**			
Varicella[8]	12 mos	**3 months**			
Hepatitis A[9]	12 mos	**6 months**			
Persons aged 7 through 18 years					
Tetanus, diphtheria/tetanus, diphtheria, pertussis[10]	7 yrs[10]	**4 weeks**	**4 weeks** if first dose administered at younger than age 12 months **6 months** if first dose administered at 12 months or older	**6 months** if first dose administered at younger than age 12 months	
Human papillomavirus[11]	9 yrs	**Routine dosing intervals are recommended**[11]			
Hepatitis A[9]	12 mos	**6 months**			
Hepatitis B[1]	Birth	**4 weeks**	**8 weeks** (and at least 16 weeks after first dose)		
Inactivated poliovirus[6]	6 wks	**4 weeks**	**4 weeks**	**6 months**	
Measles, mumps, rubella[7]	12 mos	**4 weeks**			
Varicella[8]	12 mos	**3 months** if person is younger than age 13 years **4 weeks** if person is aged 13 years or older			

1. Hepatitis B vaccine (HepB).
- Administer the 3-dose series to those not previously vaccinated.
- A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB is licensed for children aged 11 through 15 years.

2. Rotavirus vaccine (RV).
- The maximum age for the first dose is 14 weeks 6 days. Vaccination should not be initiated for infants aged 15 weeks 0 days or older.
- The maximum age for the final dose in the series is 8 months 0 days.
- If Rotarix was administered for the first and second doses, a third dose is not indicated.

3. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).
- The fifth dose is not necessary if the fourth dose was administered at age 4 years or older.

4. Haemophilus influenzae type b conjugate vaccine (Hib).
- Hib vaccine is not generally recommended for persons aged 5 years or older. No efficacy data are available on which to base a recommendation concerning use of Hib vaccine for older children and adults. However, studies suggest good immunogenicity in persons who have sickle cell disease, leukemia, or HIV infection, or who have had a splenectomy; administering 1 dose of Hib vaccine to these persons who have not previously received Hib vaccine is not contraindicated.
- If the first 2 doses were PRP-OMP (PedvaxHIB or Comvax), and administered at age 11 months or younger, the third (and final) dose should be administered at age 12 through 15 months and at least 8 weeks after the second dose.
- If the first dose was administered at age 7 through 11 months, administer the second dose at least 4 weeks later and a final dose at age 12 through 15 months.

5. Pneumococcal vaccine.
- Administer 1 dose of pneumococcal conjugate vaccine (PCV) to all healthy children aged 24 through 59 months who have not received at least 1 dose of PCV on or after age 12 months.
- For children aged 24 through 59 months with underlying medical conditions, administer 1 dose of PCV if 3 doses were received previously or administer 2 doses of PCV at least 8 weeks apart if fewer than 3 doses were received previously.
- Administer pneumococcal polysaccharide vaccine (PPSV) to children aged 2 years or older with certain underlying medical conditions, including a cochlear implant, at least 8 weeks after the last dose of PCV. See MMWR 1997;46(No. RR-8).

6. Inactivated poliovirus vaccine (IPV).
- The final dose in the series should be administered on or after the fourth birthday and at least 6 months following the previous dose.
- A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months following the previous dose.
- In the first 6 months of life, minimum age and minimum intervals are only recommended if the person is at risk for imminent exposure to circulating poliovirus (i.e., travel to a polio-endemic region or during an outbreak).

7. Measles, mumps, and rubella vaccine (MMR).
- Administer the second dose routinely at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.
- If not previously vaccinated, administer 2 doses with at least 28 days between doses.

8. Varicella vaccine.
- Administer the second dose routinely at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
- For persons aged 12 months through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
- For persons aged 13 years and older, the minimum interval between doses is 28 days.

9. Hepatitis A vaccine (HepA).
- HepA is recommended for children aged older than 23 months who live in areas where vaccination programs target older children, who are at increased risk for infection, or for whom immunity against hepatitis A is desired.

10. Tetanus and diphtheria toxoids vaccine (Td) and tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).
- Doses of DTaP are counted as part of the Td/Tdap series
- Tdap should be substituted for a single dose of Td in the catch-up series or as a booster for children aged 10 through 18 years; use Td for other doses.

11. Human papillomavirus vaccine (HPV).
- Administer the series to females at age 13 through 18 years if not previously vaccinated.
- Use recommended routine dosing intervals for series catch-up (i.e., the second and third doses should be administered at 1 to 2 and 6 months after the first dose). The minimum interval between the first and second doses is 4 weeks. The minimum interval between the second and third doses is 12 weeks, and the third dose should be administered at least 24 weeks after the first dose.

CS207330-A

Information about reporting reactions after immunization is available online at **http://www.vaers.hhs.gov** or by telephone, **800-822-7967.** Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for immunization, is available from the National Center for Immunization and Respiratory Diseases at **http://www.cdc.gov/vaccines** or telephone, **800-CDC-INFO** (800-232-4636).

Appendix 133-2
2010 Adult Immunization Schedule

Figure 2. Vaccines that might be indicated for adults based on medical and other indications

Vaccine ▼ / Indication ▶	Pregnancy	Immuno-compromising conditions (excluding human immunodeficiency virus [HIV])[3–5,13]	HIV infection[3–5,12,13] CD4+ T lympho-cyte count: < 200 cells/μL	HIV infection[3–5,12,13] CD4+ T lympho-cyte count: ≥ 200 cells/μL	Diabetes, heart disease, chronic lung disease, chronic alcoholism	Asplenia[12] (including elective splenectomy and persistent complement component deficiencies)	Chronic liver disease	Kidney failure, end-stage renal disease, receipt of hemodialysis	Healthcare personnel
Tetanus, diphtheria, pertussis (Td/Tdap)[1,*]	Td	Substitute 1-time dose of Tdap for Td booster; then boost with Td every 10 yrs							
Human papillomavirus (HPV)[2,*]		3 doses for females through age 26 yrs							
Varicella[3,*]	Contraindicated			2 doses					
Zoster[4]	Contraindicated				1 dose				
Measles, mumps, rubella (MMR)[5,*]	Contraindicated			1 or 2 doses					
Influenza[6,*]	1 dose TIV annually								1 dose TIV or LAIV annually
Pneumococcal (polysaccharide)[7,8]		1 or 2 doses							
Hepatitis A[9,*]	2 doses							2 doses	
Hepatitis B[10,*]	3 doses								
Meningococcal[11,*]	1 or more doses								

*Covered by the Vaccine Injury Compensation Program.

For all persons in this category who meet the age requirements and who lack evidence of immunity (e.g., lack documentation of vaccination or have no evidence of prior infection)

Recommended if some other risk factor is present (e.g., on the basis of medical, occupational, lifestyle, or other indications)

No recommendation

These schedules indicate the recommended age groups and medical indications for which administration of currently licensed vaccines is commonly indicated for adults ages 19 years and older, as of January 1, 2010. Licensed combination vaccines may be used whenever any components of the combination are indicated and when the vaccine's other components are not contraindicated. For detailed recommendations on all vaccines, including those used primarily for travelers or that are issued during the year, consult the manufacturers' package inserts and the complete statements from the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/pubs/acip-list.htm).

The recommendations in this schedule were approved by the Centers for Disease Control and Prevention's (CDC) Advisory Committee on Immunization Practices (ACIP), the American Academy of Family Physicians (AAFP), the American College of Obstetricians and Gynecologists (ACOG), and the American College of Physicians (ACP).

CDC

Footnotes

Recommended Adult Immunization Schedule—UNITED STATES · 2010

For complete statements by the Advisory Committee on Immunization Practices (ACIP), visit www.cdc.gov/vaccines/pubs/ACIP-list.htm.

1. **Tetanus, diphtheria, and acellular pertussis (Td/Tdap) vaccination**
   Tdap should replace a single dose of Td for adults aged 19 through 64 years who have not received a dose of Tdap previously.
   Adults with uncertain or incomplete history of primary vaccination series with tetanus and diphtheria toxoid-containing vaccines should begin or complete a primary vaccination series. A primary series for adults is 3 doses of tetanus and diphtheria toxoid-containing vaccines; administer the first 2 doses at least 4 weeks apart and the third dose 6–12 months after the second; Tdap can substitute for any one of the doses of Td in the 3-dose primary series. The booster dose of tetanus and diphtheria toxoid-containing vaccine should be administered to adults who have completed a primary series and if the last vaccination was received <10 years previously. Tdap or Td vaccine may be used, as indicated.
   If a woman is pregnant and received the last Td vaccination ≥10 years previously, administer Td during the second or third trimester. If the woman received the last Td vaccination <10 years previously, administer Tdap during the immediate postpartum period. A dose of Tdap is recommended for postpartum women, close contacts of infants aged <12 months, and all healthcare personnel with direct patient contact if they have not previously received Tdap. An interval as short as 2 years from the last Td is suggested; shorter intervals can be used. Td may be deferred during pregnancy and Tdap substituted in the immediate postpartum period, or Tdap can be administered instead of Td to a pregnant woman.
   Consult the ACIP statement for recommendations for giving Td as prophylaxis in wound management.
2. **Human papillomavirus (HPV) vaccination**
   HPV vaccination is recommended at age 11 or 12 years with catch-up vaccination at ages 13 through 26 years.
   Ideally, vaccine should be administered before potential exposure to HPV through sexual activity; however, females who are sexually active should still be vaccinated consistent with age-based recommendations. Sexually active females who have not been infected with any of the four HPV vaccine types (types 6, 11, 16, 18 all of which HPV4 prevents) or any of the two HPV vaccine types (types 16 and 18 both of which HPV2 prevents) receive the full benefit of the vaccination. Vaccination is less beneficial for females who have already been infected with one or more of the HPV vaccine types. HPV4 or HPV2 can be administered to persons with a history of genital warts, abnormal Papanicolaou test, or positive HPV DNA test, because these conditions are not evidence of prior infection with all vaccine HPV types.
   HPV4 may be administered to males aged 9 through 26 years to reduce their likelihood of acquiring genital warts. HPV4 would be most effective when administered before exposure to HPV through sexual contact.
   A complete series for either HPV4 or HPV2 consists of 3 doses. The second dose should be administered 1–2 months after the first dose; the third dose should be administered 6 months after the first dose.
   Although HPV vaccination is not specifically recommended for persons with the medical indications described in Figure 2, "Vaccines that might be indicated for adults based on medical and other indications," it may be administered to these persons because the HPV vaccine is not a live-virus vaccine. However, the immune response and vaccine efficacy might be less for persons with the medical indications described in Figure 2 than in persons who do not have the medical indications described or who are immunocompetent. Healthcare personnel are not at increased risk because of occupational exposure, and should be vaccinated consistent with age-based recommendations.
3. **Varicella vaccination**
   All adults without evidence of immunity to varicella should receive 2 doses of single-antigen varicella vaccine if not previously vaccinated or the second dose if they have received only 1 dose, unless they have a medical contraindication. Special consideration should be given to those who (1) have close contact with persons at high risk for severe disease (e.g., healthcare personnel and family contacts of persons with immunocompromising conditions) or (2) are at high risk for exposure or transmission (e.g., teachers; child-care employees; residents and staff members of institutional settings, including correctional institutions; college students; military personnel; adolescents and adults living in households with children; nonpregnant women of childbearing age; and international travelers).
   Evidence of immunity to varicella in adults includes any of the following: (1) documentation of 2 doses of varicella vaccine at least 4 weeks apart; (2) U.S.-born before 1980 (although for healthcare personnel and pregnant women, birth before 1980 should not be considered evidence of immunity); (3) history of varicella based on diagnosis or verification of varicella by a healthcare provider (for a patient reporting a history of or presenting with an atypical case, a mild case, or both, healthcare providers should seek either an epidemiologic link with a typical varicella case or to a laboratory-confirmed case or evidence of laboratory confirmation, if it was performed at the time of acute disease); (4) history of herpes zoster based on diagnosis or verification of herpes zoster by a healthcare provider; or (5) laboratory evidence of immunity or laboratory confirmation of disease.
   Pregnant women should be assessed for evidence of varicella immunity. Women who do not have evidence of immunity should receive the first dose of varicella vaccine upon completion or termination of pregnancy and before discharge from the healthcare facility. The second dose should be administered 4–8 weeks after the first dose.
4. **Herpes zoster vaccination**
   A single dose of zoster vaccine is recommended for adults aged ≥60 years regardless of whether they report a prior episode of herpes zoster. Persons with chronic medical conditions may be vaccinated unless their condition constitutes a contraindication.
5. **Measles, mumps, rubella (MMR) vaccination**
   Adults born before 1957 generally are considered immune to measles and mumps.
   Measles component: Adults born during or after 1957 should receive 1 or more doses of MMR vaccine unless they have (1) a medical contraindication; (2) documentation of vaccination with 1 or more doses of MMR vaccine; (3) laboratory evidence of immunity; or (4) documentation of physician-diagnosed measles.
   A second dose of MMR vaccine, administered 4 weeks after the first dose, is recommended for adults who (1) have been recently exposed to measles or are in an outbreak setting; (2) have been vaccinated previously with killed measles vaccine; (3) have been vaccinated with an unknown type of measles vaccine during 1963–1967; (4) are students in postsecondary educational institutions; (5) work in a healthcare facility; or (6) plan to travel internationally.
   Mumps component: Adults born during or after 1957 should receive 1 dose of MMR vaccine unless they have (1) a medical contraindication; (2) documentation of vaccination with 1 or more doses of MMR vaccine; (3) laboratory evidence of immunity; or (4) documentation of physician-diagnosed mumps.
   A second dose of MMR vaccine, administered 4 weeks after the first dose, is recommended for adults who (1) live in a community experiencing a mumps outbreak and are in an affected age group; (2) are students in postsecondary educational institutions; (3) work in a healthcare facility; or (4) plan to travel internationally.
   Rubella component: 1 dose of MMR vaccine is recommended for women who do not have documentation of rubella vaccination, or who lack laboratory evidence of immunity. For women of childbearing age, regardless of birth year, rubella immunity should be determined and women should be counseled regarding congenital rubella syndrome. Women who do not have evidence of immunity should receive MMR vaccine upon completion or termination of pregnancy and before discharge from the healthcare facility.
   Healthcare personnel born before 1957: For unvaccinated healthcare personnel born before 1957 who lack laboratory evidence of measles, mumps, and/or rubella immunity or laboratory confirmation of disease, healthcare facilities should consider vaccinating personnel with 2 doses of MMR vaccine at the appropriate interval (for measles and mumps) and 1 dose of MMR vaccine (for rubella), respectively. During outbreaks, healthcare facilities should recommend that unvaccinated healthcare personnel born before 1957, who lack laboratory evidence of measles, mumps, and/or rubella immunity or laboratory confirmation of disease, receive 2 doses of MMR vaccine during an outbreak of measles or mumps, and 1 dose during an outbreak of rubella. Complete information about evidence of immunity is available at www.cdc.gov/vaccines/recs/provisional/default.htm.
6. **Seasonal Influenza vaccination**
   Vaccinate all persons aged ≥50 years and any younger persons who would like to decrease their risk of getting influenza. Vaccinate persons aged 19 through 49 years with any of the following indications.
   Medical: Chronic disorders of the cardiovascular or pulmonary systems, including asthma; chronic metabolic diseases, including diabetes mellitus; renal or hepatic dysfunction, hemoglobinopathies, or immunocompromising conditions (including immunocompromising conditions caused by medications or HIV); cognitive, neurologic or neuromuscular disorders; and pregnancy during the influenza season. No data exist on the risk for severe or complicated influenza disease among persons with asplenia; however, influenza is a risk factor for secondary bacterial infections that can cause severe disease among persons with asplenia.
   Occupational: All healthcare personnel, including those employed by long-term care and assisted-living facilities, and caregivers of children aged <5 years.
   Other: Residents of nursing homes and other long-term care and assisted-living facilities; persons likely to transmit influenza to persons at high risk (e.g., in-home household contacts and caregivers of children aged <5 years, persons aged ≥50 years, and persons of all ages with high-risk conditions). Healthy, nonpregnant adults aged <50 years without high-risk medical conditions who are not contacts of severely immunocompromised persons in special-care units may receive either intranasally administered live, attenuated influenza vaccine (FluMist) or inactivated vaccine. Other persons should receive the inactivated vaccine.
7. **Pneumococcal polysaccharide (PPSV) vaccination**
   Vaccinate all persons with the following indications.
   Medical: Chronic lung disease (including asthma); chronic cardiovascular diseases; diabetes mellitus; chronic liver diseases, cirrhosis; chronic alcoholism; functional or anatomic asplenia (e.g., sickle cell disease or splenectomy [if elective splenectomy is planned, vaccinate at least 2 weeks before surgery]); immunocompromising conditions including chronic renal failure or nephrotic syndrome; and cochlear implants and cerebrospinal fluid leaks. Vaccinate as close to HIV diagnosis as possible.
   Other: Residents of nursing homes or long-term care facilities and persons who smoke cigarettes. Routine use of PPSV is not recommended for American Indians/Alaska Natives or persons aged <65 years unless they have underlying medical conditions that are PPSV indications. However, public health authorities may consider recommending PPSV for American Indians/Alaska Natives and persons aged 50 through 64 years who are living in areas where the risk for invasive pneumococcal disease is increased.
8. **Revaccination with PPSV**
   One-time revaccination after 5 years is recommended for persons with chronic renal failure or nephrotic syndrome; functional or anatomic asplenia (e.g., sickle cell disease or splenectomy); and for persons with immunocompromising conditions. For persons aged ≥65 years, one-time revaccination is recommended if they were vaccinated ≥5 years previously and were younger than aged <65 years at the time of primary vaccination.
9. **Hepatitis A vaccination**
   Vaccinate persons with any of the following indications and any person seeking protection from hepatitis A virus (HAV) infection.
   Behavioral: Men who have sex with men and persons who use injection drugs.
   Occupational: Persons working with HAV–infected primates or with HAV in a research laboratory setting.
   Medical: Persons with chronic liver disease and persons who receive clotting factor concentrates.
   Other: Persons traveling to or working in countries that have high or intermediate endemicity of hepatitis A (a list of countries is available at wwwn.cdc.gov/travel/contentdiseases.aspx).
   Unvaccinated persons who anticipate close personal contact (e.g., household contact or regular babysitting) with an international adoptee from a country of high or intermediate endemicity during the first 60 days after arrival of the adoptee in the United States should consider vaccination. The first dose of the 2-dose hepatitis A vaccine series should be administered as soon as adoption is planned, ideally ≥2 weeks before the arrival of the adoptee.
   Single-antigen vaccine formulations should be administered in a 2-dose schedule at either 0 and 6–12 months (Havrix), or 0 and 6–18 months (Vaqta).If the combined hepatitis A and hepatitis B vaccine (Twinrix) is used, administer 3 doses at 0, 1, and 6 months; alternatively, a 4-dose schedule, administered on days 0, 7, and 21–30 followed by a booster dose at month 12 may be used.
10. **Hepatitis B vaccination**
    Vaccinate persons with any of the following indications and any person seeking protection from hepatitis B virus (HBV) infection.
    Behavioral: Sexually active persons who are not in a long-term, mutually monogamous relationship (e.g., persons with more than one sex partner during the previous 6 months); persons seeking evaluation or treatment for a sexually transmitted disease (STD); current or recent injection-drug users; and men who have sex with men.
    Occupational: Healthcare personnel and public-safety workers who are exposed to blood or other potentially infectious body fluids.
    Medical: Persons with end-stage renal disease, including patients receiving hemodialysis; persons with HIV infection; and persons with chronic liver disease.
    Other: Household contacts and sex partners of persons with chronic HBV infection; clients and staff members of institutions for persons with developmental disabilities; and international travelers to countries with high or intermediate prevalence of chronic HBV infection (a list of countries is available at wwwn.cdc.gov/travel/contentdiseases.aspx).
    Hepatitis B vaccination is recommended for all adults in the following settings: STD treatment facilities; HIV testing and treatment facilities; facilities providing drug-abuse treatment and prevention services; healthcare settings targeting services to injection-drug users or men who have sex with men; correctional facilities; end-stage renal disease programs and facilities for chronic hemodialysis patients; and institutions and nonresidential daycare facilities for persons with developmental disabilities.
    Administer or complete a 3-dose series of HepB to those persons not previously vaccinated. The second dose should be administered 1 month after the first dose; the third dose should be administered at least 2 months after the second dose (and at least 4 months after the first dose). If the combined hepatitis A and hepatitis B vaccine (Twinrix) is used, administer 3 doses at 0, 1, and 6 months; alternatively, a 4-dose schedule, administered on days 0, 7, and 21–30 followed by a booster dose at month 12 may be used.
    Adult patients receiving hemodialysis or with other immunocompromising conditions should receive 1 dose of 40 μg/mL (Recombivax HB) administered on a 3-dose schedule or 2 doses of 20 μg/mL (Engerix-B) administered simultaneously on a 4-dose schedule at 0, 1, 2 and 6 months.
11. **Meningococcal vaccination**
    Meningococcal vaccine should be administered to persons with the following indications.
    Medical: Adults with anatomic or functional asplenia, or persistent complement component deficiencies.
    Other: First-year college students living in dormitories; microbiologists routinely exposed to isolates of *Neisseria meningitidis*; military recruits; and persons who travel to or live in countries in which meningococcal disease is hyperendemic or epidemic (e.g., the "meningitis belt" of sub-Saharan Africa during the dry season [December through June]), particularly if their contact with local populations will be prolonged. Vaccination is required by the government of Saudi Arabia for all travelers to Mecca during the annual Hajj.
    Meningococcal conjugate vaccine (MCV4) is preferred for adults with any of the preceding indications who are aged ≤55 years; meningococcal polysaccharide vaccine (MPSV4) is preferred for adults aged ≥56 years.
    Revaccination with MCV4 after 5 years is recommended for adults previously vaccinated with MCV4 or MPSV4 who remain at increased risk for infection (e.g., adults with anatomic or functional asplenia). Persons whose only risk factor is living in on-campus housing are not recommended to receive an additional dose.
12. **Selected conditions for which *Haemophilus influenzae* type b (Hib) vaccine may be used**
    Hib vaccine generally is not recommended for persons aged ≥5 years. No efficacy data are available on which to base a recommendation concerning use of Hib vaccine for older children and adults. However, studies suggest good immunogenicity in patients who have sickle cell disease, leukemia, or HIV infection or who have had a splenectomy. Administering 1 dose of Hib vaccine to these high-risk persons who have not previously received Hib vaccine is not contraindicated.
13. **Immunocompromising conditions**
    Inactivated vaccines generally are acceptable (e.g., pneumococcal, meningococcal, influenza [inactivated influenza vaccine]) and live vaccines generally are avoided in persons with immune deficiencies or immunocompromising conditions. Information on specific conditions is available at www.cdc.gov/vaccines/pubs/acip-list.htm.

CHAPTER 134

Human Immunodeficiency Virus Infection

PETER L. ANDERSON, THOMAS N. KAKUDA, AND COURTNEY V. FLETCHER

KEY CONCEPTS

1. Infection with human immunodeficiency virus (HIV) occurs through three primary modes: sexual, parenteral, and perinatal. Sexual intercourse, primarily receptive anal and vaginal intercourse, is the most common method for transmission.
2. HIV infects cells expressing cluster of differentiation 4 (CD4) receptors, such as T-helper lymphocytes, monocytes, macrophages, dendritic cells, and brain microglia. Infection occurs via an interaction between glycoprotein 120 on HIV with CD4 (primary interaction) and chemokine co-receptors (secondary interactions) present on the surfaces of these cells.
3. The hallmark of untreated HIV infection is profound CD4 T-lymphocyte depletion and severe immunosuppression that puts patients at significant risk for infectious diseases caused by opportunistic pathogens. Opportunistic infections in settings without access to antiretroviral drugs are the chief cause of morbidity and mortality associated with HIV infection.
4. General principles for the management of opportunistic infections include preventing or reversing immunosuppression with antiretroviral therapy, preventing exposure to pathogens, vaccination, prospective immunologic monitoring, primary chemoprophylaxis, treatment of acute episodes, secondary chemoprophylaxis, and discontinuation of such prophylaxes following antiretroviral therapy and subsequent immune recovery.
5. Eradication of HIV is not possible at this time. Therefore, the goal of antiretroviral therapy is to achieve maximal and durable suppression of HIV replication, interpreted to be a sustained plasma viral load less than the lower limit of quantitation. Another equally important outcome is an increase in CD4 lymphocytes because this closely correlates with the risk for developing opportunistic infections.
6. Current recommendations for the initial treatment of HIV advocate a minimum of three active antiretroviral agents from at least two drug classes. The typical regimen consists of two nucleoside analogs with either a protease inhibitor (pharmacologically enhanced with low-dose ritonavir), a nonnucleoside reverse transcriptase inhibitor, or an integrase inhibitor.
7. Clinical use of antiretroviral agents is complicated by drug–drug interactions. Some interactions are beneficial and used purposely; others may be harmful, leading to dangerously elevated or inadequate drug concentrations. For these reasons, clinicians involved in the pharmacotherapy of HIV infection must exercise constant vigilance and maintain a current knowledge of drug interactions.
8. Inadequate suppression of viral replication allows HIV to select for antiretroviral-resistant HIV variants, the major factor limiting the ability of antiretroviral drugs to inhibit virus replication and delay disease progression.
9. Current recommendations for treating drug-resistant HIV include choosing at least two drugs (preferably three) to which the patient's virus is susceptible. Susceptibility can be assessed using either (virtual) genotypic or phenotypic resistance testing.
10. The longer life span conferred by antiretroviral treatment has given rise to new medical issues. First, a wide spectrum of early aging complications have become common, some of which are adverse effects from antiretroviral drugs. Second, hepatitis C virus coinfection has emerged as an important cause of morbidity and mortality. Medical management of these contemporary HIV complications is constantly evolving.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Acquired immune deficiency syndrome (AIDS) was first recognized in a cohort of young, previously healthy homosexual men with new-onset profound immunologic deficits, *Pneumocystis carinii* (now *P. jiroveci*) pneumonia (PCP), and/or Kaposi's sarcoma. A retrovirus, human immunodeficiency virus type 1 (HIV-1), is the major cause of AIDS. A second retrovirus, HIV-2, also is recognized to cause AIDS, although it is less virulent, transmissible, and prevalent than HIV-1. These retroviruses are transmitted primarily by sexual contact and by contact with infected blood or blood products. Several risk behaviors for the acquisition of HIV infection have been identified in the United States, most notably the practice of anorectal intercourse and the sharing of blood-contaminated needles by injection-drug users. In many resource-limited countries, the majority of HIV transmission occurs via heterosexual intercourse and from childbearing women to their offspring. Initially, the medical management of HIV consisted of repeated treatments for opportunistic infections (OIs) and eventual palliative care. Single and dual antiretroviral therapies with nucleoside reverse transcriptase inhibitors (NRTIs) followed, but were not highly effective when compared with contemporary therapies. In the mid 1990s, a new era in the pharmacotherapy for HIV, known as *combination antiretroviral therapy* (ART), was born. ART consists of combinations of antiretroviral agents with different mechanisms of action that potently and durably suppress HIV replication, delay the onset of AIDS, reverse HIV-associated immunologic deficits, and significantly prolong survival. Modern antiretroviral drugs and ART regimens have improved upon tolerability and efficacy. Unfortunately,

therapeutic challenges remain in the ART era and include the need for continuous adherence to medication and care, drug–drug interactions, drug-resistant HIV, acute and long-term drug toxicities, and other complications associated with a prolonged life span. Progress has been made in the treatment access for this disease, but the worldwide picture remains grim. No strategies to date have been successful in curing HIV, and no viable vaccine is available.

HUMAN IMMUNODEFICIENCY VIRUS

EPIDEMIOLOGY

The epidemiologic characteristics of HIV infection differ according to geographic region and depend upon the mode of transmission, governmental prevention efforts and resources, and cultural factors.[1]

1 Infection with HIV occurs through three primary modes: sexual, parenteral, and perinatal. Sexual intercourse, primarily anal and vaginal intercourse, is the most common method for transmission. The probability of HIV transmission depends upon the type of sexual exposure. The highest risk appears to be from receptive anorectal intercourse at about 0.5% to 3% per sexual act.[2] Transmission risk is lower for receptive vaginal or oral intercourse and each is lower for insertive versus receptive sex acts.[3] Condom use reduces risk of transmission by approximately 20-fold.[3] Other factors that affect the probability of infection include the stage of HIV disease in the index partner. For example, transmission is higher when the index partner has early or late HIV compared with asymptomatic HIV, as these disease stages are associated with higher viral loads.[4] Individuals with genital ulcers or sexually transmitted diseases are at greater risk for contracting HIV. HIV incidence and prevalence are lower in cultures that advocate male circumcision, which is estimated to reduce risk of male acquisition of HIV during heterosexual intercourse by 60%.[4] However, male circumcision may not have the same protective effects for anal intercourse or for the female partner.[5] Casual contact with patients with AIDS or HIV infection is not a significant risk factor for HIV transmission.

Prevention of sexual transmission has focused primarily on education that encourages abstinence (especially for adolescents), use of condoms, and reduction of high-risk behavior (anal intercourse and promiscuity).[1] A combined approach has been advocated for optimal prevention. Prevention strategies under investigation include HIV vaccines, topical vaginal microbicides, and pre-exposure prophylaxis (PrEP) with antiretroviral agents.[6]

Parenteral transmission of HIV broadly encompasses infections due to infected blood exposure from needle sticks, intravenous injection with used needles, receipt of blood products, and organ transplants. Use of contaminated needles or other injection-related paraphernalia by drug abusers has been the main cause of parenteral transmissions. The risk of HIV transmission from sharing needles is approximately 0.67% per episode.[7] Prevention strategies include stopping drug abuse, obtaining needles from credible sources (e.g., pharmacies), never reusing any paraphernalia, using sterile procedures in all injecting activities, and safely disposing of used paraphernalia.[3]

Before widespread screening, HIV was readily transmitted in blood products. However, blood and tissue products in the healthcare system are now rigorously screened for HIV. The estimated risk for receiving tainted blood or blood products in the United States is approximately 1:2,000,000 and that for receiving a tainted tissue transplant is 1:55,000.[8,9] Healthcare workers have a small but definite occupational risk of contracting HIV through accidental injury. Most cases of occupationally acquired HIV have been the result of a percutaneous needle stick injury, which carries an estimated 0.3% risk of transmitting HIV. Mucocutaneous exposures (e.g., tainted blood splash in eyes, mouth, nose) carries a transmission risk of approximately 0.09%.[10] Significant risk factors for seroconversion with a needle stick include deep injury, injury with a device visibly contaminated with blood, and advanced HIV disease in the index patient (high viral load). The risk of transmission from an HIV-infected healthcare worker to a patient is extremely remote. Comprehensive medical guidelines have been developed to minimize the hazard of HIV transmission for healthcare workers and for persons exposed by rape or other means.[7,10]

Perinatal infection, or vertical transmission, is the most common cause of pediatric HIV infection.[11] Most infections occur during or near to the time of birth, although a fraction can occur in utero. The risk of mother-to-child transmission is approximately 25% in the absence of antiretroviral therapy. Factors that increase the likelihood of vertical transmission include prolonged rupture of membranes, chorioamnionitis, genital infection during pregnancy, preterm delivery, vaginal delivery, birth weight less than 2.5 kg, illicit drug use during pregnancy, and high maternal viral load. Breastfeeding also can transmit HIV. The estimated frequency of breast milk transmission is approximately 4% to 16%, with the majority of infections developing within the first 6 months.[12] High levels of virus in breast milk and in the mother are associated with higher risk of transmission.[12] Formula feeding prevents breast milk transmission of HIV but may not improve mortality from other causes early in life in some settings.[13] Whenever formula feeding is acceptable, feasible, affordable, sustainable, and safe, HIV-infected mothers are recommended not to breast-feed. A separate and comprehensive set of medical guidelines have been developed to minimize the hazard of mother-to-child HIV transmission.[11] Prevention guidelines are discussed in the Treatment of Special Population section.

Persons with HIV infection are broadly categorized as those living with HIV and those with an AIDS diagnosis. An AIDS diagnosis is made when the presence of HIV is laboratory-confirmed and the cluster of differentiation 4 (CD4; T-helper cell) count drops below 200 cells/mm^3 or after an AIDS indicator condition is diagnosed.[14] Further distinctions regarding the stage of HIV and AIDS are given in the Revised Centers for Disease Control and Prevention (CDC) surveillance case definition (Table 134–1).[14] In the United States, new HIV/AIDS cases are reported by healthcare providers to a public health department.[15] The cumulative number of reported HIV/AIDS diagnoses in the US is approximately 1.7 million; more than 550,000 persons have already died.[16] The estimated prevalence of HIV infections including AIDS cases in the United States is about 1.2 million individuals. Each year the CDC estimates that 55,000 new cases of HIV infection occur in the United States.[16] Approximately 25% of persons with HIV are unaware of their infection. The epidemic in the United States initially was established in white men who have sex with men (MSM), and the prevalence of HIV in this population still is high. New trends in transmission include more cases in women (currently ~25%) and African Americans and Hispanics, a proportion of whom are not well linked to appropriate prevention, care, and treatment services.[16] Approximately half of new cases occur in African Americans (who make up only 12% of the general population), about one third in Caucasians, and less than one fourth in Hispanics.[15] The main risk factor for transmission in women is heterosexual intercourse (~80% of cases) and injection-drug use (~20% of cases). For men the main risks are men who have sex with men (~65%), heterosexual sex (~15%), and injection-drug use (~15%).[17]

Today, the estimated number of individuals living with HIV/AIDS worldwide has stabilized at approximately 33.4 million persons, including 2.1 million children (younger than 15 years).[18,19] The new infection rate is approximately 2.7 million per year, including 430,000 children.[19] About 2 million people succumbed to AIDS in 2008. Globally, the highest concentration of HIV/AIDS cases is in sub-Saharan Africa, where approximately 22.4 million people are infected. Some African countries have HIV prevalence rates of up to 26% (e.g., Swaziland); however, other African areas have declining

TABLE 134-1 Surveillance Case Definition for HIV Infection among Adults and Adolescents (≥13 years) – United States, 2008

Stage	Laboratory evidence (laboratory-confirmed HIV infection *plus*)	Clinical evidence
Stage 1	$CD4^+$ cell count ≥500 cells/mm^3 or $CD4^+$ percentage ≥29	None required (but no AIDS-defining condition)
Stage 2	$CD4^+$ cell count 200-499 cells/mm^3 or $CD4^+$ percentage 14–28	None required (but no AIDS-defining condition)
Stage 3 (AIDS)	$CD4^+$ cell count <200 cells/mm^3 or $CD4^+$ percentage <14	or documentation of an AIDS-defining condition (with laboratory-confirmed HIV infection)
Stage unknown	no information on $CD4^+$ counts	and no information on presence of AIDS-defining conditions
AIDS indicator conditions		
Candidiasis of bronchi, trachea, or lungs	Lymphoma, Burkitt	
Candidiasis, esophageal	Lymphoma, immunoblastic	
Cervical cancer, invasive	Lymphoma, primary, for brain	
Coccidioidomycosis, disseminated or extrapulmonary	*Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary	
Cryptococcosis, extrapulmonary	*Mycobacterium tuberculosis*, any site (pulmonary or extrapulmonary)	
Cryptosporidiosis, chronic intestinal (duration >1 month)	*Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary	
Cytomegalovirus disease (other than liver, spleen, or nodes)	*Pneumocystis jirovecii* pneumonia	
Cytomegalovirus retinitis (with loss of vision)	Pneumonia, recurrent	
Encephalopathy, HIV related	Progressive multifocal leukoencephalopathy	
Herpes simplex: chronic ulcer(s) (duration >1 month); or bronchitis, pneumonitis, or esophagitis	*Salmonella* septicemia, recurrent	
Histoplasmosis, disseminated or extrapulmonary	Toxoplasmosis of brain	
Isosporiasis, chronic intestinal (duration >1 month)	Wasting syndrome due to HIV	
Kaposi sarcoma		

From reference 14.

prevalence rates (e.g., Eastern Africa) due to successful prevention strategies.[18,19] Heterosexual transmission is the most common mode of transmission in sub-Saharan Africa and worldwide (85% of cases). Women in sub-Saharan Africa and resource-limited countries are at disproportionately high risk for acquiring HIV because of biologic and cultural factors that foster HIV transmission, such as limited ability to refuse sex.[19] Other important epidemiologic features of the HIV epidemic include relatively high prevalence in Eastern Europe (e.g., Russian Federation), central Asia (e.g., Ukraine), and growing prevalence in Bangladesh and China.[18] Injection-drug use is fueling several of these epidemics.

ETIOLOGY

HIV is an enveloped single-stranded RNA virus and a member of the *Lentivirinae* (*lenti*, meaning "slow") subfamily of retroviruses. Lentiviruses are characterized by their indolent infectious cycle. There are two related but distinct types of HIV: HIV-1 and HIV-2. HIV-2, found mostly in western Africa, consists of seven phylogenetic lineages designated as subtypes (clades) A through G. HIV-1 also can be categorized based on phylogeny.[20] Three groups of HIV-1 are recognized: M (main or major), N (non-M, non-O), and O (outlier). More recently, a new HIV-1 virus was classified as group P (pending the identification of further cases).[21] The nine subtypes of HIV-1 group M are identified as A through D, F through H, and J and K. Mixtures of subtypes are referred to as *circulating recombinant forms* (CRFs). Group M, subtype B, is primarily responsible for the epidemic in North America and Western Europe.[20]

The origin of HIV is of considerable interest. The accumulated evidence suggests that HIV in humans was the result of a cross-species transmission (zoonosis) from primates infected with simian immunodeficiency virus (SIV). Phylogenetic and geographic relationships suggest that HIV-2 arose from SIV that infects sooty mangabeys and HIV-1 group M and N arose from SIVcpz, a virus that infects chimpanzees (*Pan troglodytes troglodytes*). Group O may have arisen from an SIV variant that infects wild gorillas. Cultural practices, such as preparation and eating of bush meat or keeping animals as pets, may have allowed the virus to jump from primates to humans. The earliest known human infection with HIV has been traced to central Africa in 1959, but cross-species transmissions probably date back to the early 1900s.[22] Modern transportation, promiscuity, and drug abuse have caused the rapid spread of the virus within the United States and throughout the world.[1,22] This chapter focuses on HIV-1 group M, which is the predominant strain likely to be encountered in the Western world.

DETECTION OF HIV AND SURROGATE MARKERS OF DISEASE PROGRESSION

The preferred method for diagnosing HIV-1 infection is an enzyme-linked immunosorbent assay (ELISA), which detects antibodies against HIV-1.[17] ELISA is both highly sensitive (>99%) and highly specific (>99%), but rare false-positive results can occur in multiparous women; recent recipients of hepatitis B, HIV, influenza, or rabies vaccine; patients with multiple blood transfusion, liver disease, and renal failure; or those undergoing chronic hemodialysis. False-negative results may occur and most commonly are attributed to new infection where antibody production is not yet adequate. The minimum time to develop antibodies is 3 to 4 weeks from initial exposure, with greater than 95% of individuals developing antibodies after 6 months. Convenient methods for obtaining an ELISA sample from blood or saliva have been developed, including a rapid (20–40 minutes) turnaround test.

Positive ELISA results are repeated in duplicate, and if one or both tests are reactive, a confirmatory test is performed for final diagnosis. Western blot is the most commonly used confirmatory test, although an indirect immunofluorescence assay is available. A reactive ELISA test and a positive confirmatory test indicate an established HIV infection. If the confirmatory test is indeterminate, the individual should be retested 4 weeks later.[17]

HIV testing is recommended when HIV infection is suspected because of symptoms and/or high-risk behavior. Additionally, the CDC now recommends routine HIV screening in all healthcare settings in persons 13 to 64 years, a new policy called "opt-out" testing.[17] The policy states that consent for medical care will imply consent for HIV testing; however, the person must be informed of the test and can opt out of taking it. Because states may have different

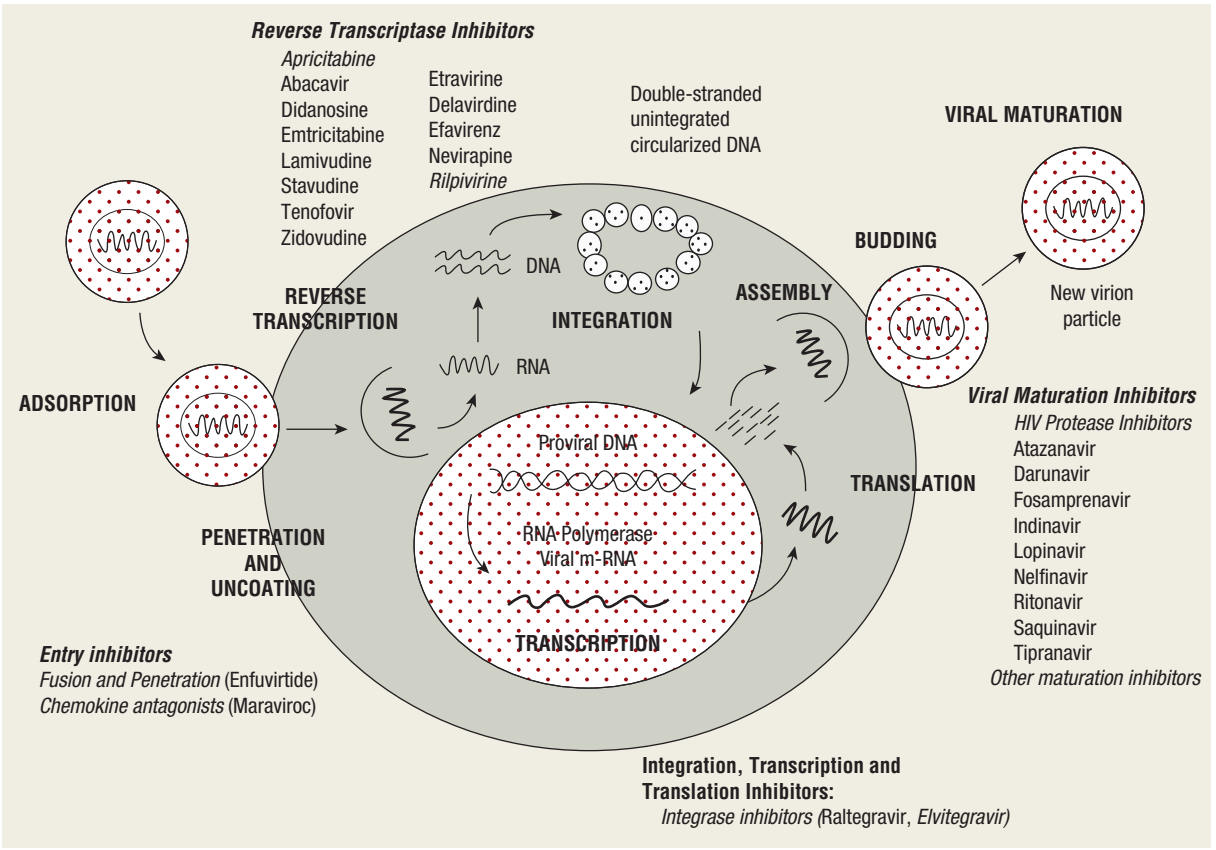

FIGURE 134-1. Life cycle of human immunodeficiency virus with potential targets where replication may be interrupted. Italicized compounds were in development at the time of this writing. *(Reprinted with permission, Courtney V. Fletcher, 2009.)*

HIV consent laws, the local requirements for HIV testing should be consulted. The rationale for the opt-out strategy is to diagnose those who unknowingly carry HIV so as to improve their prognosis and reduce further transmission.

Once diagnosed, HIV disease is monitored primarily by two surrogate biomarkers, viral load and CD4 cell count.[23] The viral load test quantifies the degree of viremia by measuring the number of copies of viral RNA (HIV RNA) in the plasma. Methods for determining HIV RNA include reverse-transcription polymerase chain reaction (RT-PCR), branched-chain DNA, transcription-mediated amplification, and nucleic acid sequence–based assay. RT-PCR is used more widely than the other techniques. Irrespective of the method used, viral load is reported as the number of viral RNA copies per milliliter of plasma. Each assay has its own lower limit of sensitivity to viral subtypes, and results can vary from one assay method to the other; therefore, it is recommended that the same assay method be used consistently within patients. Reductions in viral load often are reported in base 10 logarithm. For example, if a patient presents initially with a viral load of 100,000 copies/mL (10^5 copies/mL) and subsequently has a viral load of 10,000 copies/mL (10^4 copies/mL), the decrease in viral load is 1 $\log_{10}$. Given that HIV RNA varies within patients, a clinical response is generally considered when the decline in viral load is more than 0.5 $\log_{10}$.[23] Viral load is a major prognostic factor for monitoring disease progression and the effects of treatment.

Because HIV attacks and leads to the destruction of cells bearing the CD4 receptor, the number of CD4 lymphocytes (T-helper cells) in the blood is a critical surrogate marker of disease progression. The normal adult CD4 lymphocyte count ranges from 500 to 1,600 cells/mm^3, or 40% to 70% of total lymphocytes. CD4 counts in children are age dependent, with younger children having higher CD4 counts. The hallmark of HIV disease is depletion of CD4 cells and the associated development of OIs and malignancies.

PATHOGENESIS

2 Understanding the life cycle of HIV (Fig. 134–1) is necessary because the current strategies used for treatment of HIV target various points in this cycle. Once HIV enters the human body, the outer glycoprotein (gp160) on its surface, which is composed of two subunits (gp120 and gp41) has affinity for CD4 receptors, proteins present on the surface of T-helper lymphocytes, monocytes, macrophages, dendritic cells, and brain microglia.[24] The gp120 subunit is responsible for CD4 binding. Once initial binding occurs, the intimate association of HIV with the cell is enhanced by further binding to chemokine co-receptors. The two major chemokine receptors used by HIV are CCR5 and CXCR4. HIV isolates may contain a mixture of viruses that target one or the other of these co-receptors, and some viral strains may be dual-tropic (i.e., can use both co-receptors). The HIV strain that preferentially uses CCR5, R5 viruses, are macrophage-tropic and typically implicated in most cases of sexually transmitted HIV. Individuals with a common 32-base-pair deletion in the CCR5 gene are protected from progression of HIV disease.[25] The HIV strain that targets CXCR4, designated X4 virus, is T-cell–tropic and often is predominant in the later stage of disease. Other chemokine co-receptors and galactosyl ceramide may also serve as a binding site for HIV. CD4 and co-receptor attachment of HIV to the cell promotes membrane fusion, which is mediated by gp41, and finally internalization of the viral genetic material and enzymes necessary for replication.

After internalization, the viral protein shell surrounding the nucleic acid (capsid) is uncoated in preparation for replication.[24] The genetic material of HIV is two molecules of positive-sense (5′ to 3′) single-stranded RNA; the virus must transcribe this RNA into DNA (transcription normally occurs from DNA to RNA; HIV works backward, hence the name *retrovirus*). To do so,

HIV is equipped with the unique enzyme RNA-dependent DNA polymerase (reverse transcriptase). HIV reverse transcriptase first synthesizes a complementary strand of DNA using the viral RNA as a template. The RNA portion of this DNA–RNA hybrid is then partially removed by ribonuclease H (RNase H), allowing HIV reverse transcriptase to complete the synthesis of a double-stranded DNA molecule. The fidelity of HIV reverse transcriptase is poor, and many mistakes are made during the process. These errors in the final DNA product contribute to the rapid mutation of the virus, which enables the virus to evade the immune response (thus complicating vaccine development), and promotes the evolution of drug resistance. Following reverse transcription, the final double-stranded DNA product migrates into the nucleus and is integrated into the host cell chromosome by integrase, another enzyme unique to HIV.

The integration of HIV into the host chromosome is troublesome. Most notably, HIV can establish a persistent, latent infection, particularly in long-lived cells of the immune system such as memory T lymphocytes. The virus is effectively hidden in these cells, and this characteristic has greatly inhibited the ability to cure HIV infection. Second, random integration of HIV may cause cellular abnormalities and induce apoptosis.

After integration, HIV preferentially replicates in activated cells. Activation by antigens, cytokines, or other factors stimulates the cell to produce nuclear factor kappa B (NF-κB), an enhancer-binding protein. NF-κB normally regulates the expression of T-lymphocyte genes involved in growth but also can inadvertently activate replication of HIV. HIV encodes six regulatory and accessory proteins: Tat, Nef, Rev, Vpu, Vif, and Vpr, which enhance replication and inhibit innate immunity. For example, the Tat protein is a potent amplifier of HIV gene expression; it binds to a specific RNA sequence of HIV that initiates and stabilizes transcription elongation. Vif is a viral protein that binds human APOBEC 3G, a deoxycytidine deaminase that converts viral DNA cytosine to uracil and thereby provides innate cellular immunity.[26] Vpu inhibits tetherin, a human cellular membrane protein that prevents diffusion of virus particles after budding from infected cells, thereby allowing HIV to detach from the infected cell.[27] Assembly of new virion particles occurs in a stepwise manner beginning with the coalescence of HIV proteins beneath the host cell lipid bilayer. The nucleocapsid subsequently is formed with viral single-stranded RNA and other components packaged inside. Once packaged, the virion then buds through the plasma membrane, acquiring the characteristics of the host lipid bilayer. After the virus buds, the maturation process begins. Within the virion, protease, another enzyme unique to HIV, begins cleaving a large precursor polypeptide (gag-pol) into functional proteins that are necessary to produce a complete virus. Without this enzyme, the virion is immature and unable to infect other cells.

The characteristics of viral replication and pathogenesis exhibit three general phases, acute, chronic, and terminal (AIDS).[28,29] Recent evidence suggests that initial rounds of HIV replication during acute infection take place largely in the mucosal $CD4^+$ $CCR5^+$ T-cell pools in the gut resulting in a massive CD4 T-cell depletion in these tissues.[28,29] Cells are destroyed by a number of mechanisms, including cell lysis from newly budding virions, cytotoxic T-lymphocyte–induced cell killing, and induction of apoptosis. Following this destruction of the mucosal CD4 T cell pool, which lasts for 2 to 3 weeks, a state of heightened immune activation ensues during the chronic infection phase, which can last for several years. The activated state is characterized by high levels of activation markers on circulating T cells and pro-inflammatory cytokines and may result from HIV antigen as well as translocation of microbial antigens from the T-cell–depleted gut mucosa. Heightened activation enables further HIV replication and ultimately leads to continued depletion of $CD4^+$ $CCR5^+$ T cells. HIV-1 exhibits a very high turnover rate during this chronic phase, with an estimated 10 billion new viruses produced each day. More than 99% of these viruses are produced in newly infected activated cells. Nevertheless, the immune system is able to operate well enough during the chronic phase to prevent overt opportunistic infections that herald AIDS. Eventually, the depletion of CD4 cells and the continuous cellular activation leads to a final collapse of the immune system, or AIDS. HIV may use CXCR4 co-receptor during this last phase of infection and these viruses infect a broader range of CD4 cells (naïve and central-memory) speeding the disease progression. It is this unrelenting destruction of CD4 cells that causes the profoundly compromised immune system and AIDS.[28,29]

TABLE 134-2 Clinical Presentation of HIV Infection

Symptoms
Fever, sore throat, fatigue, weight loss, myalgia
40% to 80% of patients exhibit a morbilliform or maculopapular rash usually involving the trunk
Diarrhea, nausea, vomiting
Lymphadenopathy, night sweats
Aseptic meningitis (fever, headache, photophobia, stiff neck) may be present in 25% of presenting cases
Other
High viral load (may exceed 1,000,000 copies per milliliter)
Persistent decrease in CD4 lymphocytes

CLINICAL PRESENTATION

3 Clinical presentation of primary HIV infection varies, but most patients (40%–90%) have an acute retroviral syndrome or mononucleosis-like illness (Table 134–2).[30] Symptoms often last 2 weeks, and hospitalization may be required for 15% of patients. Primary infection is associated with a high viral load (>10^6 copies/mL) and a precipitous drop in CD4 cells. After several weeks an immune response is mounted, the amount of HIV RNA in plasma falls substantially, and symptoms resolve gradually. However, as described above, this clinically latent period is not virologically latent because HIV replication is continuous (~10 billion viruses per day) and immune system destruction is ongoing. A steady decrease in CD4 cells is the most measurable aspect of this immune system deterioration. Plasma viral load, on the other hand, will appear to have stabilized at a particular level or "set point." The set point that is established correlates directly with the time to AIDS and morbidity. The Multicenter AIDS Cohort Study measured viral load in 181 HIV-positive men and followed them for as long as 11 years. The mortality rates within 5 years for those with a viral load below 4530 copies/mL was 5% compared with 49% for those with a viral load above 36,270 copies/mL.[31] Thus, a higher viral set point is associated with poorer prognosis. Not all individuals infected with HIV progress to AIDS—these so-called "long-term non-progressors" may be infected with a defective virus (e.g., nef-deficient HIV) or may have an intrinsic ability to resist infection (e.g., CCR5 mutation).[25]

Most children born with HIV are asymptomatic. On physical examination, children often present with nonspecific signs, such as lymphadenopathy, hepatomegaly, splenomegaly, failure to thrive, weight loss or unexplained low birth weight (in prenatally exposed infants), and fever of unknown origin.[32] Laboratory findings include anemia, hypergammaglobulinemia (primarily immunoglobulin [Ig] A and IgM), altered mononuclear cell function, and altered T-cell subset ratios. Of note, the normal range for CD4 cell counts in young children is much different from the range in adults (Table 134–3).[33] Children have different susceptibility and/or exposures to OIs compared with adults.[32] Bacterial infections, including *Streptococcus pneumoniae*, *Salmonella* spp, and *Mycobacterium tuberculosis*,

TABLE 134-3 Centers for Disease Control and Prevention 1994 Revised Classification System for Human Immunodeficieny Virus Infection in Children Younger Than 13 Years

Immunologic Categories	12 Month CD4 Cells/mm³ (%[a])	1–5 Years CD4 Cells/mm³ (%[a])	6–12 Years CD4 Cells/mm³ (%[a])	
1. No evidence of suppression	≥1,500 (≥25%)	≥1,000 (≥25%)	≥500 (≥25%)	
2. Evidence of moderate suppression	750–1,499 (15%–24%)	500–999 (15%–24%)	200–499 (15%–24%)	
3. Severe suppression	<750 (<15%)	<500 (<15%)	<200 (<15%)	
Immunologic Categories	**N: No Signs/Symptoms**	**A: Mild Signs/Symptoms**	**B: Moderate Signs/Symptoms**	**C: Severe Signs/Symptoms**
1. No evidence of suppression	N1	A1	B1	C1
2. Evidence of moderate suppression	N2	A2	B2	C2
3. Severe suppression	N3	A3	B3	C3

[a]Percentage of total lymphocytes.
From reference 33.

may be more prevalent in children with AIDS than in adults with the disease. Kaposi sarcoma is rare in children. Children with HIV infection may develop lymphocytic interstitial pneumonitis without evidence of *P. jiroveci* or other pathogens on lung biopsy. Some children (~25%) will progress to AIDS rapidly within the first year of life. A presentation of serious opportunistic infections such as *P. jiroveci* pneumonia, encephalopathy, failure to thrive, and a precipitous drop in CD4 cells are common in these infants.[32] The current CDC pediatric AIDS surveillance definition (see Table 134–3) excludes children with congenital or perinatally acquired cytomegalovirus or other identified causes of congenital immunodeficiency; laboratory-confirmed HIV-infection is required.[14,33] General management of the HIV-infected child involves principles similar to those used for the adult: antiretroviral therapy, treatment and prophylaxis of OIs, and supportive care.[34,35]

TREATMENT

DESIRED OUTCOME

5 The central goals of antiretroviral therapy are to decrease morbidity and mortality, improve quality of life, restore and preserve immune function, and prevent further transmission. The most important and effective way to achieve these goals is maximal suppression of HIV replication, which is interpreted as plasma HIV RNA less than the lower limit of quantitation (i.e., undetectable; usually <50 copies/mL).[23] Such a profound reduction in HIV RNA is associated with long-term response to therapy (i.e., durability) as well as increases in CD4 lymphocytes, which closely correlates with the risk for developing OIs. While undetectable HIV RNA almost always corresponds with a rise in CD4 lymphocytes, some patients respond virologically or immunologically without the other. [23]

GENERAL APPROACH TO TREATMENT

4 Prior to 1996, HIV infection was treated with one or two nucleoside analog reverse transcriptase inhibitors, which were generally not effective at controlling viremia. Thus, the mainstay of treatment was pharmacologic management of OIs and palliative care. At that time, the prognosis for HIV infection was dire and most patients were disabled and eventually died. In 1995, HIV protease inhibitors (PIs) were introduced followed by non-nucleoside analog reverse transcriptase inhibitors (NNRTIs), and a new paradigm in HIV treatment was born. Combinations of three active antiretroviral agents from two pharmacologic classes were shown to profoundly inhibit HIV replication, prevent and reverse immune deficiency, and substantially decrease morbidity and mortality—constituting the ART era.[36] At the same time, multiple other major medical advances were introduced, such as the discovery that HIV establishes a long-lived reservoir in chronically infected cells, and the viral load test (plasma HIV-RNA). With this backdrop of dramatic changes, in 1997 the National Institutes of Health Office of AIDS Research convened a panel to define the scientific principles that might serve as a guide for the clinical use of antiretroviral agents.[37] The 11 principles presented here are an amalgamation of knowledge of the life cycle of HIV, the consequences of HIV replication, clinical trials of antiretroviral agents, and scientific opinion. These foundational principles are still relevant today.

1. Ongoing HIV replication leads to immune system damage and progression to AIDS. HIV infection is always harmful, and true long-term survival free of clinically significant immune dysfunction is unusual.
2. Plasma HIV RNA levels indicate the magnitude of HIV replication and its associated rate of CD4 cell destruction, whereas CD4 cell counts indicate the extent of HIV-induced immune damage already suffered. Regular periodic measurement of plasma HIV RNA levels and CD4 cell counts is necessary to determine the risk of disease progression in an HIV-infected individual and to determine when to initiate or modify antiretroviral treatment regimens.
3. Because rates of disease progression differ among individuals, treatment decisions should be individualized by level of risk indicated by plasma HIV RNA levels and CD4 cell counts.
4. Use of potent combination antiretroviral therapy to suppress HIV replication to below the levels of detection of sensitive plasma HIV RNA assays limits the potential for selection of antiretroviral-resistant HIV variants, the major factor limiting the ability of antiretroviral drugs to inhibit virus replication and delay disease progression. Therefore, maximum achievable suppression of HIV replication should be the goal of therapy.
5. The most effective means for accomplishing durable suppression of HIV replication is simultaneous initiation of combinations of effective anti-HIV drugs with which the patient has not been treated previously and that are not cross-resistant with antiretroviral agents with which the patient has been treated previously.
6. Each of the antiretroviral drugs used in combination therapy regimens always should be used according to optimal schedules and dosages.
7. The available effective antiretroviral drugs are limited in number and mechanism of action, and cross-resistance between specific drugs has been documented. Therefore, any change in antiretroviral therapy increases future therapeutic constraints.

8. Women should receive optimal antiretroviral therapy regardless of pregnancy status.
9. The same principles of antiretroviral therapy apply to both HIV-infected children and adults, although treatment of HIV-infected children involves unique pharmacologic, virologic, and immunologic considerations.
10. Persons with acute primary HIV infections should be treated with combination antiretroviral therapy to suppress virus replication to levels below the limit of detection of sensitive plasma HIV RNA assays.
11. HIV-infected persons, even those with viral loads below detectable limits, should be considered infectious and should be counseled to avoid sexual and drug-use behaviors that are associated with transmission or acquisition of HIV and other infectious pathogens.

The extent to which these 11 principles will continue to stand the test of time is unknown; new information on the pathogenesis and treatment of HIV accrues constantly. One continuing source of controversy is whether to treat patients with acute HIV infection. As of December 2009, 25 distinct antiretroviral compounds have been approved by the U.S. Food and Drug Administration (FDA); one (zalcitabine) has since been removed from the market. Table 134–4 presents the state of the art for treatment of HIV-infected individuals as of December 2009.[23] Treatment is recommended for all HIV-infected persons with a history of an AIDS-defining event, symptomatic disease, or a CD4 lymphocyte count below 350 cells/mm^3. Therapy is also recommended for asymptomatic patients with CD4 counts between 350 and 500 cells/mm^3, and some clinicians would also favor starting therapy in those with >500 CD4 cells/mm^3. Other indications for therapy at any CD4 count include pregnancy, HIV-associated nephropathy, or when treatment is needed for hepatitis B co-infection.

CLINICAL CONTROVERSY

Treatment of persons with acute primary HIV infection with combination antiretroviral therapy to suppress virus replication to levels below the limit of detection of sensitive plasma HIV RNA assays is controversial. Well-designed trials with clinical end points that define the long-term safety and efficacy of initiating combination antiretroviral therapy during acute HIV infection are lacking. Theoretical benefits are decreasing the severity of acute disease; perhaps lowering the initial viral load setpoint, which affects progression rates; preserving immune function; and reducing the risk for viral transmission. However, these potential benefits must be weighed against the issues imposed by early intervention of chronic therapy, which would be many years ahead of normal initiation of therapy (discussed below).

The optimal time to initiate therapy in chronic HIV infection has also been a matter of debate over the last 10 years. The relative risk of death in asymptomatic HIV-infected individuals is higher when antiretroviral therapy is delayed. Among individuals with a CD4 count of 351 to 500 cells/mm^3 prior to therapy, a 69% increase in the risk of death was found if treatment was deferred until their CD4 cell count fell below 350 cells/mm^3 compared to those initiating immediate treatment; similarly, deferring therapy until the CD4 cell count fell below 500 cells/mm^3 was associated with a 94% increase in the risk of death.[38] Healthcare professionals involved in the care of HIV-infected persons must consult the most current literature on the principles and strategies for therapy. Better patient outcomes are demonstrated when clinicians have significant HIV expertise. Likewise, the patient must be ready and willing to commit to life-long treatment including an understanding of its risks and benefits and the need to maintain a high level of adherence. An excellent source for information on treatment guidelines, which is regularly updated, is available at *www.AIDSinfo.NIH.gov*. Additional guidelines and electronic resources for HIV clinicians are provided in reference 17.

CLINICAL CONTROVERSY

The precise time to start therapy is controversial. Early in the ART era, the mantra was "hit early and hit hard," with hopes that the drugs would be well tolerated and the virus could be eradicated. When it became clear that treatment was long term and that these earlier drugs had potential long-term side effects, the mantra changed to a drug-sparing paradigm where therapy was initiated as late as possible. Newer agents have improved upon tolerability, but lack long-term safety data. The benefits of early therapy include preventing the known detriments of unchecked viral replication, including irreversible immune damage and increased likelihood of viral transmission. The potential risks of initiating combination antiretroviral therapy include the lifestyle demands of continuous therapy, drug toxicities, and development of antiretroviral drug resistance.

PHARMACOLOGIC THERAPY

Conceptually the four primary methods of therapeutic intervention against HIV are inhibition of viral replication, microbicides to prevent HIV infection, vaccination to stimulate a more effective immune response, and restoration of the immune system with immunomodulators; the latter three approaches are mostly investigational. Several approaches for an HIV vaccine are in development, including whole killed virus, subunit and peptide vaccination, recombinant live vector, and naked DNA delivery. A randomized placebo-controlled trial demonstrated a modest 30% reduction in HIV transmission in a modified-intention to treat analysis of ALVAC-HIV plus AIDSVAX vaccine in 16,402 volunteers (P=0.04).[39] The modified analysis excluded subjects who were found to be HIV-infected prior to randomization. However, the efficacy difference was not significant in the per-protocol analysis (P=0.16). Therefore, the findings must be considered tentative until more definitive data become available. Overall, progress has been slow for the vaccine field. Genetic variability in HIV and a nascent understanding of the role of the immune system in suppressing viral replication are significant barriers to the development of an effective HIV vaccine with long-lasting and protective immunity. Immunomodulators, such as aldesleukin (interleukin 2), provide mild benefits in terms of increased CD4 cells, however, aldesleukin is also associated with significant toxicities and no apparent clinical benefit.[40] Additional immunotherapies are in earlier phases of study. Microbicides for use vaginally or rectally to prevent sexual transmission of HIV are in various phases of development.[41]

Antiretroviral Agents

6 Inhibiting viral replication with combinations of potent antiretroviral agents has been the most clinically successful strategy. Four general classes of drugs are used today: entry inhibitors, reverse transcriptase inhibitors, integrase strand transfer inhibitors and HIV protease inhibitors (Table 134–5).[23,42,43] Reverse transcriptase inhibitors consist of two classes: those that are chemical derivatives

TABLE 134-4 Treatment of Human Immunodeficiency Virus Infection: Antiretroviral Regimens Recommended in Antiretroviral-Naïve Persons

	Preferred Regimens	Limitation
NNRTI based	Efavirenz + tenofovir + emtricitabine (AI)	Not in first trimester of pregnancy or in women without adequate contraception
PI based	Darunavir + ritonavir + tenofovir + emtricitabine (AI)	Caution in HCV–HBV co-infection, rash
	Atazanavir + ritonavir + tenofovir + emtricitabine (AI)	Not with high doses of proton-pump-inhibitors, rash
	Raltegravir + tenofovir + emtricitabine (AI)	Twice daily (not once daily)
Alternative regimens (some potential disadvantages versus preferred regimens)		
	Efavirenz + (abacavir or zidovudine) + lamivudine (BI)	Possible reduced efficacy for high viral loads (abacavir), more subcutaneous fat loss (zidovudine)
	Nevirapine + zidovudine + lamivudine (BI)	Not in moderate to severe hepatic disease or in women with CD4 >250 cells/mm^3 or men with CD4 >450 cells/mm^3
PI based	Atazanavir-ritonavir + (abacavir or zidovudine) + lamivudine (BI)	See above
	Lopinavir-ritonavir (once or twice daily) either with (abacavir or zidovudine) + lamivudine or (tenofovir+ emtricitabine) (BI)	Gastrointestinal intolerance, lipids
	Fosamprenavir/ritonavir (once or twice daily) either with (abacavir or zidovudine) + lamivudine or (tenofovir + emtricitabine) (BI)	Rash
	Saquinavir-ritonavir (twice daily) + tenofovir + emtricitabine (BI)	High number of pills/complexity
Acceptable regimens (potential additional disadvantages or pending additional data)		
	Efavirenz + didanosine + (lamivudine or emtricitabine) (CI)	Mitochondrial toxicities with didanosine
	Atazanavir + (abacavir or zidovudine) + lamivudine (CI)	Lower atazanavir concentrations compared with atazanavir-ritonavir
	Maraviroc + zidovudine + lamivudine (CIII)	Lower virologic activity versus efavirenz, need tropism test
	Raltegravir + abacavir or zidovudine + lamivudine	See above
	(Darunavir-ritonavir or saquinavir-ritonavir) + (abacavir or zidovudine) + lamivudine	See above
Regimens or components that should not be used		
Regimen or component		**Comment**
Any all NRTI regimen (EI)		Inferior virologic efficacy
Abacavir + didanosine or abacavir + tenofovir (DIII)		Insufficient data
Didanosine + tenofovir (EII)		Inferior virologic efficacy, CD4 declines
Stavudine (EI)		Toxicity including subcutaneous fat loss, peripheral neuropathy, and lactic acidosis
Darunavir or tipranavir or saquinavir without ritonavir (EI)		Insufficient plasma concentrations and efficacy or not studied
Delavirdine (EII)		Inferior virologic efficacy and inconvenient dosing
Enfuvirtide (DIII)		Not studied in naïve patients, inconvenient injections
Etravirine (DIII)		Not studied in naïve patients
Indinavir with or without ritonavir (EIII)		Nephrolithiasis, fluid requirements and inconvenient
Nelfinavir (without ritonavir) (EI)		Inferior virologic efficacy
Ritonavir at virologic doses (EIII)		Gastrointestinal intolerance
Tipranavir-ritonavir (EI)		Inferior virologic efficacy

NRTI, nucleoside reverse transcriptase inhibitor.
Evidence-based Rating Definition
Rating Strength of Recommendation:
A: Both strong evidence for efficacy and substantial clinical benefit support recommendation for use; should always be offered.
B: Moderate evidence for efficacy or strong evidence for efficacy but only limited clinical benefit, supports recommendation for use; should usually be offered.
C: Evidence for efficacy is insufficient to support a recommendation for or against use, or evidence for efficacy might not outweigh adverse consequences (e.g., drug toxicity, drug interactions) or cost of treatment under consideration; use is optional.
D: Moderate evidence for lack of efficacy or for adverse outcome supports recommendation against use; should usually not be offered.
E: Good evidence for lack of efficacy or for adverse outcome supports a recommendation against use; should never be offered.
Rating Quality of Evidence Supporting the Recommendation:
I: Evidence from at least one correctly randomized, controlled trial with clinical outcomes and/or validated laboratory endpoints.
II: Evidence from at least one well-designed clinical trial without randomization or observational cohorts with long-term clinical outcomes.
III: Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of consulting committees.
[a]Lamivudine and emtricitabine are considered interchangeable.

of purine- and pyrimidine-based nucleosides and nucleotides (nucleoside/nucleotide reverse transcriptase inhibitors [NRTIs]) and those that are not (nonnucleoside reverse transcriptase inhibitors [NNRTIs]). NRTIs include the thymidine analogs stavudine (d4T) and zidovudine (AZT or ZDV); the deoxycytidine analogs emtricitabine (FTC) and lamivudine (3TC); the deoxyguanosine analog abacavir sulfate (ABC); and the deoxyadenosine analogs of which didanosine (ddI) is an inosine derivative and tenofovir disoproxil fumarate (TDF) is a deoxyadenosine-monophosphate nucleotide analog (a nucleotide is a nucleoside with one or more phosphates). **Note that drug abbreviations are provided here and below for reference, but their use is discouraged because they may lead to prescribing or administration errors.** As a class, the NRTIs require phosphorylation to the 5′-triphosphate moiety to become

TABLE 134-5 Selected Pharmacologic Characteristics of Antiretroviral Compounds

Drug	F (%)	$t_{1/2}$(h)[a]	Adult Dose[b] (doses/day)	Plasma C_{max}/ C_{min} (μM)	Distinguishing Adverse Effect
Integrase inhibitors (InSTI)					
Raltegravir	?	9	400 mg (2)	1.74/0.22	Increased creatine kinase
Nucleoside (Nucleotide) reverse transcriptase inhibitors (NRTIs)					
Abacavir	83	1.5/20	300 mg (2)	5.2/0.03	Hypersensitivity
			or		
			600 mg (1)	7.4[c]	
Didanosine	42	1.4/24	200 mg (2)	2.8/0.03	Peripheral neuropathy, pancreatitis
			or		
			400 mg (1)	5.6[c]	
Emtricitabine	93	10/39	200 mg (1)	7.3/0.04	Pigmentation on soles and palms in non-whites
Lamivudine	86	5/22	150 mg (2)	6.3/1.6	Headache, pancreatitis (children)
			or		
			300 mg (1)	10.5/0.5	
Stavudine	86	1.4/7	40 mg (2)	2.4/0.04	Lipoatrophy, peripheral neuropathy
Tenofovir	40	17/150	300 mg (1)	1.04/0.4	Renal toxicity (proximal tubule)
Zidovudine	85	2/3.5	200 mg (3)	0.2	Anemia, neutropenia, myopathy
			or		
			300 mg (2)	3[c]	
Nonnucleoside reverse transcriptase inhibitors (NNRTIs)					
Delavirdine	85	5.8	400 mg (3)	35/14	Rash, elevated liver function tests
			or		
			600 mg (2)		
Efavirenz	43	48	600 mg (1)	12.9/5.6	Central nervous system disturbances and teratogenicity
Etravirine	?	41	200 mg (2)	1.69/0.86	Rash, nausea
Nevirapine	93	25	200 mg (2)[d]	22/14	Potentially serious rash and hepatotoxicity
Protease inhibitors (PIs)					
Amprenavir[e]	?	9	1,400 mg (2)[e]	9.5/0.7	Rash
	or		*or*		
Forsamprenavir[e]			1,400 mg (1)[e,f]	14.3/2.9	
Atazanavir	68	7	400 mg (1)	3.3/0.23	Unconjugated hyperbilirubinemia
			or		
			300 mg (1)[f]	6.2/0.9	
Darunavir	82	15	800 mg (1) or 600 mg (2)[f]	11.9/6.5	Hepatitis, rash
Indinavir	60	1.5	800 mg (3)	13/0.25	Nephrolithiasis
			or		
			400–800 mg (2)[f]		
Lopinavir[g]	?	5.5	800 mg (1) or 400 mg (2)	13.6/7.5	Hyperlipidemia/GI intolerance
Nelfinavir	?	2.6	750 mg (3)	5.3/1.76	Diarrhea
			or		
			1,250 mg (2)	7/1.2	
Ritonavir	60	3–5	600 mg (2)[d]	16/5	Gastrointestinal intolerance
			or		
			"Boosting doses"		
Saquinavir	4	3	1,000 mg (2)[f]	3.9/0.55	Mild nausea, bloating
Tipranavir	?	6	500 mg (2)[f]	77.6/35.6	Hepatoxocity, intracranial hemorrhage
Entry inhibitorsFusion inhibitor					
Enfuvirtide	84	3.8	90 mg (2)	1.1/0.73	Injection-site reactions
Co-receptor inhibitor					
Maraviroc	33	15	300 mg (2)	1.2/0.066	Hepatitis, allergic reaction

C_{max}, maximum plasma concentration; C_{min}, minimum plasma concentration; F, bioavailability; $t_{1/2}$, elimination half-life.
[a]NRTIs: Plasma NRTI $t_{1/2}$/intracellular (peripheral blood mononuclear cells) NRTI-triphosphate $t_{1/2}$; plasma $t_{1/2}$ only for other classes.
[b]Dose adjustment may be required for weight, renal or hepatic disease, and drug interactions.
[c]C_{min} concentration typically below the limit of quantification.
[d]Initial dose escalation recommended to minimize side effects.
[e]Fosamprenavir is a tablet phosphate prodrug of amprenavir. Amprenavir is available only as oral solution.
[f]Must be boosted with low doses of ritonavir (100–200 mg).
[g]Available as coformulation 4:1 lopinavir to ritonavir.
Data from Department of Health and Human Services (DHHS) Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the use of antiretroviral agents in HIV-infected adults and adolescents; December 1, 2009; references 42 and 43, and product information for agents.

pharmacologically active. Intracellular phosphorylation occurs by cytoplasmic or mitochondrial kinases and phosphotransferases (not viral kinases). The 5′-triphosphate moiety acts in two ways: (a) it competes with endogenous deoxyribonucleotides for the catalytic site of reverse transcriptase, and (b) it prematurely terminates DNA elongation as it lacks the requisite 3′-hydroxyl for sugar-phosphate linking.[42] Although NRTI tri-phosphates (or diphosphate for tenofovir) are specific for HIV reverse transcriptase, their adverse effects may be caused in part by inhibition of mitochondrial DNA or RNA synthesis.[44] Toxicities include peripheral neuropathy, pancreatitis, lipoatrophy (subcutaneous fat loss), myopathy, anemia, and rarely life-threatening lactic acidosis with fatty liver.[45] Use of stavudine

and didanosine has declined in favor of more tolerable NRTIs (e.g., emtricitabine, lamivudine and tenofovir).[23] With some exceptions, NRTIs are mainly eliminated by the kidney and dose adjustments are required for renal insufficiency. Resistance has been reported for all NRTIs, including cross-resistance within the class as multiple and/or specific mutations accrue.[46]

NNRTIs are a chemically heterogeneous group of agents that bind noncompetitively to reverse transcriptase adjacent to the catalytic site. Unlike NRTIs, NNRTIs do not require intracellular activation, do not compete against endogenous deoxyribonucleotides, and do not have potent antiviral activity against HIV-2. Given the different site of binding to reverse transcriptase, NNRTIs can be used with NRTIs effectively. Available NNRTIs include efavirenz (EFV), delavirdine (DLV), nevirapine (NVP) and etravirine (ETR).[23] As a class, the NNRTIs are generally associated with rash and elevated liver function tests, including life-threatening cases rarely, particularly for nevirapine.[44] NNRTIs tend to have long plasma half-lives and are mainly cleared by liver and/or gut-mediated metabolism through the cytochrome P450 enzyme system. The NNRTIs are unique in that a single mutation is needed to confer high-level cross-resistance for the class (except etravirine), which has been termed a *low-genetic barrier* to resistance.[46]

The HIV protease inhibitors (PIs) include amprenavir (APV) and its prodrug fosamprenavir (FPV), atazanavir (ATV), darunavir (DRV), indinavir (IDV), lopinavir (LPV), nelfinavir (NFV), ritonavir (RTV), saquinavir (SQV), and tipranavir (TPV). PIs competitively inhibit the cleavage of the gag-pol polyprotein, which is a crucial step in the viral maturation process, thereby resulting in the production of immature, noninfectious virions. PIs are generally associated with gastrointestinal distress and metabolic changes, such as increased lipids, insulin insensitivity, and changes in body fat distribution.[45] PIs are cleared by liver- and gut-mediated metabolism (mainly CYP3A). PIs are almost always used with small doses of ritonavir, a CYP3A inhibitor, to enhance the plasma concentrations of the PI of interest. CYP3A-mediated drug interactions are important considerations for PIs. Resistance to the PIs generally requires the buildup of multiple mutations, termed a *high-genetic barrier*. Multiple mutations can lead to cross-resistance.[46]

There are currently two types of entry inhibitors: fusion inhibitors and CCR5 antagonists. Enfuvirtide (ENF) is the only fusion inhibitor available at this time. Enfuvirtide is a synthetic 36-amino-acid peptide that binds gp41, which inhibits fusion of HIV with the target cell. Because of the peptide nature of enfuvirtide, oral delivery is impossible, and subcutaneous injection is the preferred route of administration. Injection-site reactions are the most common adverse effect. Enfuvirtide is cleared via protein catabolism and amino acid recycling. Enfuvirtide appears to have a low genetic barrier to resistance.[46] Maraviroc is CCR5 antagonists. Unlike the other available antiretrovirals which target a viral protein (i.e., enzyme), CCR5 antagonists block a human receptor. The long-term consequences of blocking CCR5 are unknown but may include increased susceptibility to infection by flavivirus (e.g., West Nile virus and tickborne encephalitis virus).[47] One advantage of targeting a human receptor is that resistance to CCR5 antagonists may be more difficult to develop. Because CCR5 antagonists are only effective against R5 virus and not X4 virus, a viral tropism assay should be performed prior to using a CCR5 antagonist. Whether long-term use of CCR5 antagonists shifts viral tropism from predominantly R5 to the more pathogenic X4 strain remains to be determined. Maraviroc is a CYP3A substrate; a substrate of P-glycoprotein, thus it is susceptible to drug–drug interactions.

Raltegravir is the first integrase strand transfer inhibitor (InSTIs) to be FDA approved and marketed with elvitegravir and other compounds under development. InSTIs bind to HIV integrase while it is in a specific complex with viral DNA. As a result, viral DNA cannot become incorporated into the human genome and cellular enzymes degrade unincorporated viral DNA. Alternatively, recombination and repair mechanisms may form long-terminal repeat (LTR) circular DNA from the unincorporated viral DNA. Raltegravir is primarily glucuronidated by UGT1A1 and is not broadly susceptible to CYP-mediated drug interactions. Elvitegravir is first metabolized by CYP3A then glucuronidated and is thus susceptible to CYP3A drug interactions. Higher elvitegravir plasma concentrations are achieved when coadministered with either low-dose ritonavir or the novel CYP3A inhibitor, cobicistat under development.[48]

Novel antiviral agents in the classes listed above and novel agents in new drug classes that exploit other steps in the HIV life cycle (see Fig. 134–1) are in development, with a focus on activity against drug-resistant virus.[49] For example, drugs that block steps in the maturation or assembly of HIV other than protease cleavage are under development. New drugs including cobicistat that increase the plasma concentrations of CYP3A substrates such as PIs are also in development.[48]

Interestingly, the antimalarials chloroquine and hydroxychloroquine exert anti–HIV-1 and anti–HIV-2 activity through interference with gp120 (HIV envelope glycoprotein) during assembly.[50] The antivirals acyclovir and foscarnet exhibit modest anti-HIV activity via inhibition of HIV reverse transcriptase.[51,52]

Drug Interactions

❼ Medical use of antiretroviral agents is complicated by clinically significant drug–drug interactions that can occur with many of these agents.[23,53] Some interactions are beneficial and used purposely (e.g., ritonavir); others may be harmful, leading to dangerously elevated or inadequate drug concentrations. Clinicians involved in the pharmacotherapy of HIV must understand the mechanistic basis for these interactions and maintain a current knowledge of drug interactions for these reasons.

Many clinically significant antiretroviral-associated drug interactions involve CYP3A-mediated metabolism and clearance. The PIs, except nelfinavir, the NNRTIs delavirdine and etravirine, the CCR5 antagonist maraviroc, and the InSTI elvitegravir are metabolized by CYP3A. In general, efavirenz, etravirine and nevirapine are inducers of CYP3A, whereas delavirdine and the PIs inhibit CYP3A. Ritonavir is a potent inhibitor of CYP3A-mediated metabolism and is now used almost exclusively at lower doses as a pharmacokinetic enhancer of other PIs.[48] Darunavir, lopinavir, saquinavir, and tipranavir must be taken with ritonavir to achieve optimal plasma concentrations. Atazanavir, fosamprenavir, and indinavir are also primarily used with ritonavir for the same reason. Nelfinavir is not effectively boosted by ritonavir given its CYP2C19-mediated metabolism. Many potential concomitant drugs on the market are also metabolized by CYP3A and therefore susceptible to clinically relevant drug interactions with PIs and NNRTIs.[23,53] Agents with narrow therapeutic indices and/or that exhibit major changes in pharmacokinetics with CYP3A inhibition are most important in this regard. Examples include, but are not limited to, simvastatin, lovastatin, corticosteroids, ergot derivatives, and some antiarrhythmics. The drug interaction potential of antimycobacterium agents, specifically the rifamycins, are particularly relevant given the high potential for such infections in HIV-infected patients.[53] Rifampin, a potent inducer of CYP3A metabolism and conjugation enzymes, is contraindicated with use of most PIs, etravirine, and maraviroc because concentrations are reduced substantially even with ritonavir enhancement. Raltegravir dose should be doubled in the presence of rifampin; efavirenz is an alternative agent. Ritonavir enhancement generally allows coadministration of PIs and rifabutin.[53] In such cases, the rifabutin dose will require adjustment given its CYP3A-mediated clearance.

The herbal product St. John's wort (*Hypericum perforatum*) is a potent inducer of metabolism and is contraindicated with PIs, NNRTIs, and maraviroc.[23] It must be stressed that the pharmacology of CYP3A interactions may be complicated by simultaneous induction/inhibition of drug transporter-mediated (e.g., P-glycoprotein) clearance and or other phase I or phase II enzymes. Clinicians who treat HIV must stay abreast of antiretroviral drug interaction data. The Department of Health and Human Services guidelines for antiretroviral use provide, and regularly update, excellent summaries of known clinically relevant drug interactions.[23,53]

NRTIs are not metabolized by CYP3A, but other drug interaction considerations are important. Generally, NRTIs of the same nucleobase should not be coadministered. For example, zidovudine and stavudine are both thymidine analogs and phosphorylated by the same cellular enzymes. Antagonism occurs between these two drugs both in vitro and in vivo; thus, the two should never be given together. Similarly, deoxycytidine analogs should not be coadministered. The deoxyadenosine analogs didanosine and tenofovir exhibit a plasma drug interaction whereby didanosine concentrations are significantly increased.[23] Furthermore, the two adenosine analogs are less effective together compared with other recommended NRTI regimens and there is concern for CD4 lymphotoxicity, a troubling effect that appears unique to this NRTI combination. Coadministration of didanosine and tenofovir is not recommended for initial therapy.[23]

Landmarks in the Evolution of Antiretroviral Therapy

Antiretroviral therapy has undergone major changes over the past decades. Illustrating these changes is important for a thorough understanding of current treatment strategies. The fundamental landmarks in the use of antiretroviral agents are as follows:

- An early study demonstrated that zidovudine monotherapy confers a survival benefit in persons who have AIDS.[54] This study showed that a single drug provided moderate clinical benefit.
- Further investigation showed that combination regimens of two NRTIs (e.g., zidovudine and didanosine or zalcitabine) were superior to zidovudine monotherapy in immunologic and virologic parameters, particularly in patients with no previous antiretroviral therapy, and conferred a superior survival benefit.[55] This established that NRTI monotherapy was inferior to dual NRTI therapy.
- A pivotal study showed that dual NRTI therapy was inferior to triple therapy consisting of 2 NRTIs and the PI indinavir.[56] Use of triple therapy with combinations of two NRTIs with NNRTIs or PIs was associated with a durable response as well as significantly reduced incidence of OIs and improved survival, thus establishing the current paradigm of ART. [57]
- Evolution of triple-therapy regimens with a boosted PI or efavirenz showed superior virologic efficacy versus unboosted PIs and triple NRTI regimens.[58,59] Further studies demonstrated that certain ART regimens provided slightly better virologic efficacy, safety/tolerability, and or dosing convenience compared with other three-drug regimens.

6 Taken together, the pivotal studies described above established that HIV should not be treated with single or dual NRTIs. Current recommendations for initial treatment of HIV infection advocate a minimum of three active antiretroviral agents: Tenofovir disoproxil fumarate plus emtricitabine with either a ritonavir-enhanced PI (darunavir or atazanavir), the NNRTI efavirenz, or the InSTI raltegravir.[23] Multiple alternative regimens are also safe and effective, but have one or two disadvantages compared with the preferred regimens, such as weaker virologic responses with high viral loads, lower tolerability, or greater risk of long-term toxicities such as subcutaneous fat loss. Preferred and alternative antiretroviral regimens are listed in Table 134–4.[23] The World Health Organization (WHO) also updated its treatment recommendations for resource-limited settings. The main updates to the WHO guidelines are the recommendation to treat at higher CD4 count thresholds (350 cell/mm^3) and not to include stavudine as initial therapy.[60]

A great number of considerations go into choosing the optimal drug regimen for a given patient. A resistance test is generally recommended when the patient enters HIV care and the results should help guide therapy. Other considerations include avoidance of PIs in patients taking contraindicated concomitant medications such as rifampin (efavirenz would be an alternative), avoidance of tenofovir in patients with pre-existing renal dysfunction (abacavir would be an alternative), and avoidance of efavirenz in fertile women not on stable and reliable contraception (PIs would be an alternative). The most convenient regimen is a once-daily fixed-dose combination formulation of efavirenz–tenofovir disoproxil fumarate–emtricitabine. Other antiretrovirals are also available in fixed-dose combinations to minimize the number of pills required per dose. Several factors contribute to whether the patient will mount a durable response to initial therapy, including adherence, pharmacologic effectiveness, and tolerability.

The simplest definition of adherence is the patient's ability to take medication as directed. Antiretroviral therapy is complex and long term, and the risk for virologic failure increases as adherence decreases.[61] As clinicians, it is critical to establish a relationship of trust with the patient and to communicate to the patient the importance of proper medication taking. Education should be aimed at understanding the disease process, monitoring, and goals of therapy. An individual's "readiness" to take medications should be clearly established before any treatment is initiated.[23] Help from caregivers, friends, and/or family members should be leveraged by the patient because social and psychological support are among the most important factors that influence adherence in this patient population.

Based on clinical trial data, approximately 70% to 90% of patients will achieve undetectable viral loads with modern ART regimens. Tenofovir disoproxil fumarate and emtricitabine (tenofovir-emtricitabine) has emerged as the preferred NRTI combination.[62–65] An open-labeled trial of 517 antiretroviral naïve patients randomized to tenofovir-emtricitabine versus zidovudine-lamivudine both with efavirenz demonstrated that significantly more patients in the tenofovir-emtricitabine arm achieved less than 400 copies/mL of HIV-RNA at 48 weeks (84%) compared with patients randomized to zidovudine-lamivudine (73%).[63] CD4 increases were also significantly greater in the tenofovir-emtricitabine versus zidovudine-lamivudine group. Part of this difference was attributed to more patients discontinuing zidovudine-lamivudine due to adverse events compared with tenofovir-emtricitabine. Subcutaneous fat loss and lipid elevations were also higher in the zidovudine- lamivudine group through 48 weeks. A slight decrease in glomerular filtration rate was observed in the tenofovir-emtricitabine group versus a slight increase in the zidovudine-lamivudine group. Another randomized study compared abacavir-lamivudine to tenofovir-emtricitabine in a blinded manner in combination with either efavirenz or atazanavir/ritonavir (open labeled) in 1858 antiretroviral naïve adults. Among subjects with >100,000 copies/mL of plasma HIV-RNA at screening, those randomized to abacavir-lamivudine experienced twice

the virologic failure rate and significantly more adverse events compared with those randomized to tenofovir-emtricitabine.[66] Other studies have also evaluated virologic efficacy and safety of abacavir-lamivudine in subjects with >100,000 copies/mL at baseline and have found high rates of efficacy and safety regardless of baseline viral load.[67] Taken together, these studies have solidified tenofovir-emtricitabine as the first line NRTI combination, as well as efavirenz-tenofovir-emtricitabine as a first line regimen for antiretroviral naïve patients.

The STARTMRK study was a randomized, placebo-controlled, multi-center comparison of efavirenz versus raltegravir, both with tenofovir-emtricitabine, in 566 antiretroviral naïve adults.[62] In the intent-to-treat analysis, 86% of subjects had <50 copies/mL at 48 weeks in the raltegravir group versus 82% of subjects in the efavirenz group (noninferiority $P<0.0001$). The mean CD4 increase at week 48 was 189 and 163 cells/mm^3, respectively ($P=0.02$), and the time to reach <50 copies/mL was faster in the subjects randomized to raltegravir. About half as many subjects randomized to raltegravir had an adverse effect of moderate-to-severe intensity compared with those randomized to efavirenz. This study led to the inclusion of raltegravir-tenofovir-efavirenz as a preferred regimen for initial treatment of HIV-infection.

The ARTEMIS trial was a noninferiority, open-labeled, randomized study of darunavir-ritonavir once daily versus lopinavir-ritonavir either once or twice daily all in combination with tenofovir-emtricitabine in 689 antiretroviral naïve adults.[64] At week 48, 84% versus 78% of subjects had HIV-RNA levels <50 copies/mL in the darunavir-ritonavir and lopinavir-ritonavir groups, respectively (noninferiority $P<0.001$). CD4 responses were similar between the two groups, however, the virologic response was higher for darunavir-ritonavir in those with >100,000 copies/mL of HIV-RNA at baseline. More subjects in the lopinavir-ritonavir group experienced gastrointestinal intolerance and lipid elevations. The CASTLE study was another noninferiority, open-labeled, randomized trial that compared atazanavir-ritonavir to lopinavir-ritonavir (twice daily) both with tenofovir-emtricitabine in 883 antiretroviral-naïve adults.[65] At 48 weeks, 78% and 76% of subjects in the respective groups achieved <50 copies/mL (noninferiority $P<0.001$). CD4 responses were similar in the two groups as were responses in subjects with high viral loads at baseline. More subjects in the lopinavir-ritonavir group experienced gastrointestinal intolerance and high lipids whereas more subjects in the atazanavir-ritonavir group experienced asymptomatic hyperbilirubinemia from atazanavir's inhibition of UGT1A1. These studies established darunavir-ritonavir and atazanavir-ritonavir both with tenofovir-efavirenz as preferred first-line regimens for HIV-infection and, along with other studies, moved lopinavir-ritonavir to an alternative regimen.[68]

Patients with sustained undetectable HIV-RNA taking out-of-date drug regimens may be candidates to simplify to one of the preferred regimens or a more desirable alternative regimen based on past treatment history and other variables. If abacavir is to be used in any regimen, a test for the presence of human leukocyte antigen (HLA) B*5701 should be done as its presence has been strongly correlated with the development of abacavir hypersensitivity. Should this test be positive, an abacavir allergy should be added to the patient's chart and abacavir should not be used in the patient. Similarly, a tropism test is required prior to using maraviroc to establish that the patient's virus uses the CCR5 co-receptor.[23]

Finally, because of the risk of side effects and resistance associated with NRTIs and NNRTIs, several trials have assessed ritonavir boosted PI monotherapy. In general, this strategy is inferior to three drug regimens unless the patient has been virologically suppressed for at least 6 months.[69] Ritonavir-boosted PI monotherapy cannot be advocated at this time.[23]

Resistance

8 Regimen failure is commonly associated with antiretroviral resistance, and testing for such resistance is a useful clinical tool.[46] The two types of resistance tests available are phenotype and genotype. A phenotype test determines the concentration of antiretroviral necessary to inhibit 50% replication of the patient's viral isolate (inhibitory concentration of 50% [IC_{50}]) in a recombinant in vitro viral assay. Results usually are expressed as a fold change in susceptibility (IC_{50}) compared with a wild-type laboratory strain virus. Generally, the fold-change in IC_{50} increases as HIV accumulates additional mutations that confer resistance to a particular drug. However, a single mutation may confer a very high fold-change in IC_{50} for some drugs (e.g., lamivudine, emtricitabine, efarvirenz, nevirapine) rendering them ineffective after a single mutation. Although small to moderate increases in the fold change suggests reduced susceptibility to that antiretroviral agent, resistance may not be absolute, and partial susceptibility may remain. Theoretically, drug levels may be increased to overcome reduced susceptibility; this strategy is currently under evaluation. The strengths of phenotypic testing is to provide resistance information for complex mutation patterns, but it is also associated with higher cost, limited number of commercial providers, and slower turnaround time for results. Genotyping assesses genetic mutations and associated codon changes in gp41, reverse transcriptase, integrase or protease in the patient's virus and compares it to the wild-type sequence. Mutations, when present, are listed by the wild-type amino acid followed by the position in the genetic sequence of the protein or enzyme and end with the mutation found in the patient. For example, a common mutation caused by lamivudine and emtricitabine is the M184V mutation: a substitution of valine (V) for methionine (M) at the 184 position of reverse transcriptase. Mutations can confer varying degrees of antiretroviral drug resistance and in some cases, weighting algorithms have been developed to predict the relative impact of mutation combinations on antiretroviral activity. Algorithms have also been developed to predict a phenotype from a genotype test (i.e., virtual phenotype). Not all mutations, however, are only detrimental — for example, while M184V confers significant resistance to lamivudine and emtricitabine, it is also associated with a less fit virus.[70] New genetic mutations are discovered occasionally and interpretation of genotypes resistance tests is complex, therefore the reader is encouraged to consult the most recent guidelines on HIV resistance testing.[46]

Treatment of Special Populations

PREGNANCY

Several considerations are relevant to the treatment of pregnant women, including the health of the mother, prevention of HIV transmission to the fetus, potential for teratogenicity, and dosing issues based on pharmacokinetic changes during pregnancy. Treatment recommendations should be consulted to address the specific requirements for HIV-infected pregnant women and the prevention of vertical transmission.[11] Generally, pregnant women should be treated as would nonpregnant women, with some exceptions. For example, efavirenz should not be used, particularly in the first trimester, because of potential teratogenicity. Zidovudine prophylaxis is generally recommended as part of treatment regimens based on early studies demonstrating clear prophylactic effectiveness as well as extensive familiarity with the side-effect profile.[11] Infants also receive zidovudine prophylaxis for 6 weeks after birth. Lopinavir-ritonavir has also been studied extensively in pregnant

women, and is recommended in this population. Currently, HIV transmission rates have been reduced to <2% for women who are treated with ART and when zidovudine prophylaxis is used.[11]

In resource-limited settings or when HIV infection is detected very close to delivery, an abbreviated course of zidovudine (i.e., given during labor or in the first 48 hours of the baby's life) also can reduce transmission substantially and may be easier for the patient to take. Alternatively, single-dose nevirapine given to the mother during labor and to the baby within 3 days of birth can reduce transmission of HIV; however, the risk of nevirapine resistance in the mother is considerable (and in infants who become HIV-infected), occurring in nearly 60% of cases.[71] The high risk likely is due to the low genetic barrier to resistance for nevirapine coupled with the long decay half-life and subsequent prolonged suboptimal concentrations. Resistance from single-dose nevirapine in mothers can be reduced from approximately 60% to 9% with the addition of 4 to 7 days of zidovudine-lamivudine.[71]

POSTEXPOSURE PROPHYLAXIS

Protection of healthcare workers from accidental exposure to HIV and in cases of rape or high-risk postcoital and postinjection drug-use episodes are important concerns. The CDC has issued guidelines governing treatment of occupational and other high risk HIV exposures.[7,10] These guidelines should be consulted for updates as the knowledge in this field evolves. The principles of the guidelines are to grade the exposure risk and treat as soon as possible after high-risk exposures to prevent HIV infection. The makeup of the treatment depends upon the risk. Postexposure prophylaxis (PEP) with a triple-drug regimen consisting of two NRTIs and a boosted-PI is recommended for percutaneous blood exposure involving significant risk (e.g., large-bore needle, visible blood from patients with advanced AIDS). Two NRTIs may be offered to the healthcare worker with lower risk of exposure, such as cases involving superficial exposures to the mucous membrane or broken skin. Urine, saliva, nasal secretions, stool, and sputum are not considered infectious unless visibly contaminated with blood. The optimal duration of treatment is unknown, but at least 4 weeks of therapy is advocated. Treatment ideally should be initiated within 1 to 2 hours of exposure, but treatment is recommended up to 72 hours postexposure. Expert consultation is needed when exposure to drug-resistant virus is suspected or confirmed, but this should not delay initiation of postexposure prophylaxis.[7,10]

Preexposure prophylaxis (PrEP) is under phase III study for reducing HIV transmission. The concept is to prevent HIV infection by treating persons at high risk for HIV exposure with antiretrovirals before they are actually exposed. Tenofovir-emtricitabine are the agents under most study at this time. However, this strategy cannot be recommended until safety and efficacy information become available.

EVALUATION OF THERAPEUTIC OUTCOMES

Two laboratory tests are used to evaluate response to antiretroviral therapy: the plasma HIV RNA and the CD4 count.[23] After therapy is initiated, patients are generally monitored at 3-month intervals, although an assessment at 2 to 8 weeks is warranted to document early response. The two main indications for a change in therapy are significant toxicity and treatment failure. Should a single agent be responsible for an intolerable side effect, that agent often can be singly changed out of the regimen; for example, the patient who experiences intolerable central nervous system disturbances during initiation of efavirenz can switch to a boosted PI without changing the dual NRTI backbone. Caution must be exercised when drugs in the regimen have overlapping toxicities, which makes changing a single agent problematic. Serious and life-threatening toxicities warrant cessation of the whole regimen before deciding upon a subsequent therapy.

As a general guide, the following events indicate treatment failure and should prompt consideration for changing therapy:

1. Less than 1 $\log_{10}$ reduction in HIV RNA 1 to 4 weeks after initiation of therapy or a failure to achieve less than 400 copies/mL by 24 weeks or less than 50 copies/mL by 48 weeks.
2. After HIV RNA suppression, repeated detection of HIV-RNA.
3. Failure to achieve a rise in CD4 of 25 to 50 cells/mm^3 by 48 weeks.
4. Clinical disease progression, usually the development of a new OI.

THERAPEUTIC FAILURE

9 Therapeutic failure can be defined by suboptimal suppression of viral replication, inadequate immunological recovery, or the development of AIDS-defining conditions. Many reasons may underlie therapeutic failure such as nonadherence to medication, development of drug resistance, intolerance to one or more medications, adverse drug–drug or drug–food interactions, or pharmacokinetic–pharmacodynamic variability.[23] In cases of therapeutic failure, these potential causes should be investigated and addressed, if possible. As a general rule, drug resistance develops for regimens that do not maximally suppress HIV replication. Drug resistance testing is recommended while the patient is undergoing the failing regimen or within 4 weeks after stopping the regimen as long as the HIV RNA count is greater than 500 copies/mL, which is the threshold for resistance assays (~500–1,000 copies/mL).[46] Most clinicians use the genotype assay because it is less expensive and results typically are available sooner compared with the phenotype assay. Resistance results usually require expert interpretation. Treating patients with drug resistant HIV utilizes many of the same general treatment approaches described for initial therapy above. Patients should be treated with at least two (preferably three) fully active antiretroviral drugs based on medication history, resistance tests, and new mechanistic drug classes (e.g., maraviroc, enfuvirtide, raltegravir). The goal of therapy is to suppress HIV-RNA to <50 copies/mL. In cases when <50 copies/mL cannot be attained, maintenance on the regimen is preferred over drug discontinuation so as to prevent rapid immunological and clinical decline.

Several recently approved drugs are active against highly resistant HIV.[23] For example, the two newest PIs darunavir and tipranavir and the newest NNRTI, etravirine are active against multidrug-resistant HIV in controlled trials. The drugs in the newer drug classes, raltegravir, maraviroc, and enfuvirtide are also active against NRTI, NNRTI, and PI resistant viruses in highly treatment experienced patients in controlled trials.

Previous strategies for therapeutic failure have proven largely ineffective, including drug holidays, structured or strategic treatment interruptions, and structured intermittent therapy. The overall premise of these strategies was similar: stop all antiretrovirals and allow the patient time off medication. Reinitiation of therapy was intended to reestablish control of viral replication, as wild-type virus would be expected to predominate, although the resistant virus is likely archived in long-lived cells. A landmark clinical trial tested the hypothesis that episodic antiretroviral therapy guided by the CD4 count would lower morbidity and mortality, including that associated with drug toxicity compared with continuous therapy.[72] However, the patients randomized to episodic therapy (drug-sparing) experienced significantly increased risk of opportunistic

disease or death from any cause, including non-AIDS causes.[73] Most morbidity and mortality were consequences of lowering the CD4 count and increasing the viral load, but increased drug-related toxicity was also observed. Thus, episodic drug sparing did not reduce the risk of adverse events that have been associated with antiretroviral therapy, and drug-sparing approaches are generally not advocated. Finally, it is important to consider the implications of stopping all drugs simultaneously for regimens containing drugs with short half-lives (e.g., zidovudine) as well as drugs with long half-lives (e.g., efavirenz and nevirapine). The result may be functional monotherapy for the drug with a long half-life once the shorter half-life drugs are cleared, which can lead to resistance mutations especially for drugs with low genetic barriers (e.g., NNRTIs).[74] At this time, the optimal time sequence for staggered component discontinuation has not been determined.

CLINICAL CONTROVERSY

There is a compelling theoretical rationale for therapeutic drug monitoring in the experienced patient, but this approach is currently controversial. Drug susceptibility is founded on the premise that increasing drug concentration corresponds with stronger inhibition of replication up to a maximal effectiveness. This principle holds for drug-resistant variants, except higher drug concentrations are needed for the same levels of inhibition. Therefore, drug concentration monitoring could guide dose adjustments needed to attain the higher target drug concentrations required for optimal viral inhibition. Currently, therapeutic drug monitoring is suggested as a consideration for patients with multidrug-resistant HIV as well as in other select clinical situations. However, limitations to therapeutic drug monitoring include the lack of established target concentrations, intrapatient pharmacokinetic variability, lack of randomized clinical trials proving benefit or cost effectiveness, and few analytical laboratories and experts available for interpretation. Most antiretrovirals are not suitably formulated for minor dose adjustments.

COMPLICATIONS OF HIV INFECTION AND AIDS

3 In the pre-ART era, the major therapeutic focus was prevention and treatment of opportunistic infections associated with uncontrolled HIV replication and a steady decline in CD4 cells.[36] Uncontrolled HIV is an insidious disease; persons infected often present with OIs, a consequence of the weakened immune system rather than HIV per se. Most OIs are caused by organisms that are common in the environment and often represent the reactivation of quiescent, hidden infections common in the population. The probability of developing specific OIs is closely related to CD4 count thresholds (Fig. 134–2). These CD4 thresholds serve as a basis for initiating primary OI chemoprevention.

4 In the ART era, the main principle in the management of OIs is treating HIV infection to enable CD4 cell recovery and maintenance above safe levels.[53] Additional important principles regarding management of OIs are as follows:

1. Prevent exposure to opportunistic pathogens
2. Vaccinations to prevent first-episode disease (consult HIV-specific guidelines)
3. Primary chemoprophylaxis at certain CD4 thresholds to prevent first-episode disease
4. Treat emergent OI
5. Secondary chemoprophylaxis to prevent disease recurrence
6. Discontinuation of certain prophylaxes with sustained ART-associated immune recovery

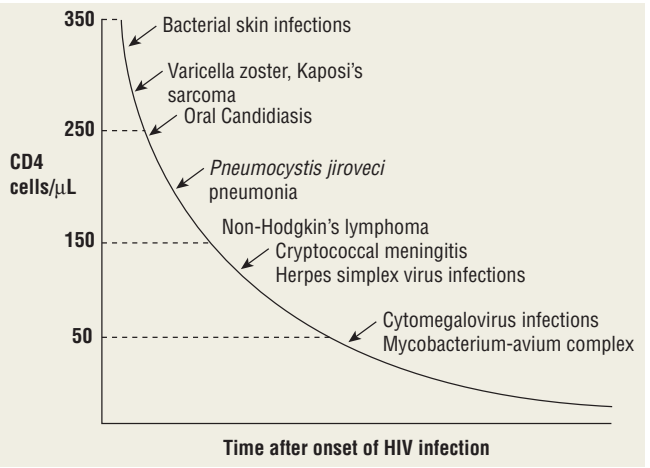

FIGURE 134-2. Natural history of opportunistic infections associated with human immunodeficiency virus infection. *(Reprinted with permission, © Courtney V. Fletcher, 2009.)*

Several considerations are required for the patient who presents with an OI and is simultaneously diagnosed with HIV and who thus needs both OI and ART treatment.[53] Immediate initiation of ART is indicated for OIs that respond to CD4 recovery, such as cryptosporidiosis, progressive multifocal leukoencephalopathy, and Kaposi sarcoma. However, for other OIs such as tuberculosis, *Mycobacterium avium* complex (MAC), and PCP, several potential problems complicate the timing of when to initiate ART relative to OI therapy. First, drug–drug interactions and the complexity of adhering to concomitant regimens can be daunting. Second, potentially overlapping drug toxicities can hand-tie clinicians trying to stop specific drugs thought to be eliciting the toxicity event. Third, an immune reconstitution syndrome (IRIS) has been associated with initiation of ART in the presence of underlying OIs. Although the reaction has not been systematically defined, IRIS is generally characterized by fever and worsening of OI manifestations in the initial 4 to 8 weeks after ART, and the reaction may take weeks to months to resolve.[53] Risk factors for IRIS are a low CD4 count, a rapid virologic response to ART, and a high antigenic burden.[75] An ART-associated rapid-onset immune reconstitution against the smoldering OI infection is thought to be the mechanism of IRIS. Treatment of IRIS is supportive, but may also include interruption of ART or antiinflammatory drugs.[75]

The AIDS Clinical Trials A5164 study compared immediate versus deferred ART in subjects treated for an acute OI (63% PCP, 12% Cryptococcal meningitis, 12% bacterial infections). Subjects had advanced HIV infection with an average CD4 count of 29 cells/mm^3 and viral load >100,000 copies/mL. Subjects with tuberculosis were excluded. The immediate ART arm (n=141) initiated ART within 12 days after OI treatment was started versus within 45 days for the deferred ART arm (n=141). The rate of AIDS progression or death was significantly greater in the deferred ART arm compared with early ART arm (14% vs 24%; P=0.035). IRIS was reported in only 7% of subjects; 8 in the early ART arm and 12 in the deferred ART arm. On the basis of these findings, clinicians should consider early initiation of ART in subjects in the setting of these OIs provided there are no contraindications.[76] However, clinicians must make such decisions on a case-by-case basis.

The three major OIs (PCP, MAC, and Cytomegalovirus retinitis) all have decreased substantially in incidence with the

TABLE 134-6 Therapies for Common Opportunistic Pathogens in HIV-Infected Individuals

Clinical Disease	Preferred Initial Therapies for Acute Infection in Adults (Strength of Recommendation in Parentheses)	Common Drug- or Dose-Limiting Adverse Reactions
Fungi		
Candidiasis, oral	Fluconazole 100 mg orally for 7–14 days (AI)	Elevated liver function tests, hepatotoxicity, nausea and vomiting
	or	
	Nystatin 500,000 units oral swish (~5 mL) 4 times daily for 7–14 days (BII)	Taste, patient acceptance
Candidiasis, esophageal	Fluconazole 100–400 mg orally or IV daily for 14–21 days (AI)	Same as above
	or	
	Itraconazole 200 mg/day orally for 14–21 days (AI)	Elevated liver function tests, hepatotoxicity, nausea and vomiting
Pneumocystis jiroveci pneumonia	Trimethoprim–sulfamethoxazole IV or orally 15–20 mg/kg/day as trimethoprim component in 3–4 divided doses for 21 days[a] (AI) moderate or severe therapy should be started IV	Skin rash, fever, leucopenia, thrombocytopenia
	or	
	Pentamidine IV 4 mg/kg/day for 21 days[a] (AI)	Azotemia, hypoglycemia, hyperglycemia, arrhythmias
	Mild episodes	
	Atovaquone suspension 750 mg (5 mL) orally twice daily with meals for 21 days[a] (BI)	Rash, elevated liver enzymes, diarrhea
Cryptococcal meningitis	Amphotericin B 0.7 mg/kg/day IV for a minimum of 2 weeks with flucytosine 100 mg/kg/day orally in four divided doses (AI) *followed by*	Nephrotoxicity, hypokalemia, anemia, fever, chills, Bone marrow suppression, Elevated liver enzymes
	Fluconazole 400 mg/day, orally for 8 weeks or until CSF cultures are negative (AI)[a]	Same as above
Histoplasmosis	Liposomal amphotericin B 3 mg/kg/day IV for 3–10 days (AI) *followed by*	Same as above
	Itraconazole 200 mg orally thrice daily for 3 days, then twice daily for 12 months[a] (AII)	
Coccidioidomycosis	Amphotericin B 0.7–1 mg/kg/day IV until clinical improvement (usually after 500–1,000 mg) then switch to azole (AII)[a]	Same as above
	followed by	
	Fluconazole 400–800 mg once daily (meningeal disease) (AII)[a]	Same as above
Protozoa		
Toxoplasmic encephalitis	Pyrimethamine 200 mg orally once, then 50–75 mg/day	Bone marrow suppression
	plus	
	Sulfadiazine 1–1.5 g orally 4 times daily	Allergy, rash, drug fever
	and	
	Leucovorin 10–25 mg orally daily for 6 weeks (AI)[a]	
Isosporiasis	Trimethoprim and sulfamethoxazole: 160 mg trimethoprim and 800 mg sulfamethoxazole orally or IV 4 times daily for 10 days (AII)[a]	Same as above
Bacteria		
Mycobacterium avium complex	Clarithromycin 500 mg orally twice daily, *plus* ethambutol 15 mg/kg/day orally (AI), *and*	Gastrointestinal intolerance, optic neuritis, peripheral neuritis
	For advanced disease, rifabutin 300 mg/day (dose may need adjustment with ART) (AI)[a]	Rash, gastrointestinal intolerance, Neutropenia, discolored urine, uveitis
Salmonella enterocolitis or bacteremia	Ciprofloxacin 500–750 mg orally (or 400 mg IV) twice daily for 14 days (longer duration for bacteremia or advanced HIV) (AIII)	Gastrointestinal intolerance
Campylobacter enterocolitis	Ciprofloxacin 500 mg orally twice daily	Same as above
	or	
	Azithromycin 500 mg orally daily for 7 days (or 14 days with bacteremia) (BIII)	
Shigella enterocolitis	Ciprofloxacin 500 mg orally twice daily for 5 days (or 14 days for bacteremia) (AIII)	Same as above
Viruses		
Mucocutaneous herpes simplex	Acyclovir 5 mg/kg IV every 8 hours until lesions regress, then acyclovir 400 mg orally 3 times daily until complete healing (famciclovir or valacyclovir is alternative) (AII)	Gastrointestinal intolerance, crystalluria
Primary varicella-zoster	Acyclovir 10–15 mg/kg every 8 hours IV for 7–10 days, then switch to oral acyclovir 800 mg 5 times daily after defervescence (famciclovir or valacyclovir is alternative) (AIII)	Obstructive nephropathy, central nervous system symptomatology
Cytomegalovirus (retinitis)	Ganciclovir intraocular implant *plus* valganciclovir 900 mg twice daily for 14-21 days then once daily until immune recovery from ART (AI)[a]	Neutropenia, thrombocytopenia
Cytomegalovirus esophagitis or colitis	Ganciclovir 5 mg/kg IV every 12 hours for 21 to 28 days (BII)	Same as above

ART, antiretroviral therapy; CSF, cerebrospiral fluid; HIV, human immunodeficiency virus.
[a]Maintenance therapy is recommended.
See Table 134–4 for levels of evidence-based recommendations.
From reference 53.

advent of ART.[36,53] Furthermore, primary and secondary chemoprophylaxes for OIs have contributed to the same decreases. Nevertheless, opportunistic diseases continue to be complications of HIV disease and occur at low CD4 lymphocyte counts in patients who are unaware of their HIV infection, or who have not responded to ART therapy or OI prophylaxis because of adherence issues or inadequate engagement with the healthcare system.[53]

The spectrum of OIs observed in HIV-infected individuals and recommended first-line regimens for treatment are given in Table 134–6. Recommended therapies for primary prophylaxis are given in Table 134–7.[53] These lists of recommendations are not as

TABLE 134-7 Therapies for Prophylaxis of Select First-Episode Opportunistic Diseases in Adults and Adolescents

Pathogen	Indication	First Choice (Strength of Recommendation in Parentheses)
I. Standard of care		
Pneumocystis jiroveci	CD4+ count <200/mm³ *or* oropharyngeal candidiasis	Trimethoprim–sulfamethoxazole, one double-strength tablet orally once daily (AI) or 1 single-strength tablet orally once daily (AI)
Mycobacterium tuberculosis		
Isoniazid sensitive	(Active TB should be ruled out): + test for latent TB infection with no prior TB treatment history *or* - test for latent TB infection, but close contact with case of active tuberculosis *or* history of untreated or inadequately treated healed TB regardless of latent TB infection test results	Isoniazid 300 mg orally plus pyridoxine, 50 mg orally once daily for 9 months (AII) *or* Isoniazid 900 mg orally twice weekly (BII) plus pyridoxine 50 mg orally daily for 9 months (BIII)
For exposure to drug resistant TB	Consult public health authorities	
Toxoplasma gondii	Immunoglobulin G antibody to *Toxoplasma* and CD4+ count <100/mm³	Trimethoprim–sulfamethoxazole, one double-strength tablet orally once daily (AII)
Mycobacterium avium complex	CD4+ count <50/mm³	Azithromycin 1,200 mg orally once weekly (AI) or 600 mg orally twice weekly (BIII) or clarithromycin 500 mg orally twice daily (AI)
Varicella zoster virus (VZV)	Pre-exposure: CD4 ≥200/mm³, no history of varicella infection, or, if available, negative antibody to VZV	Varicella vaccination; two doses, three months apart (CIII)
	Postexposure: Significant exposure to chicken pox or shingles for patients who have no history of either condition or, if available, negative antibody to VZV	Varicella-zoster immune globulin, 125 IU per 10 kg (maximum of 625 IU) IM, within 96 hours after exposure to a person with active varicella or herpes zoster (AIII)
Streptococcus pneumoniae	CD4 count ≥200 cells/mm³ or no receipt of vaccination in past 5 years. Consider for those with CD4 <200/mm³ and those with an CD4 increase to >200/mm³ on ART (CIII)	23-valent polysaccharide vaccine, 0.5 mL intramuscularly (BII) revaccination every 5 years may be considered (CIII)
Hepatitis B virus	All susceptible patients	Hepatitis B vaccine, three doses (AII). Anti-HBs should be obtained one month after the vaccine series completion (BIII)
Influenza virus	All patients (annually, before influenza season)	Inactivated trivalent influenza virus vaccine (annual): 0.5 mL intramuscularly (AIII)
Hepatitis A virus	All susceptible (anti–hepatitis A virus–negative) patients at increased risk for hepatitis A infection (e.g., chronic liver disease, illegal drug users, men who have sex with men)	Hepatitis A vaccine: two doses (AII) antibody response should be assessed 1 month after vaccination; with revaccination as needed (BIII)
Human papillomavirus (HPV) infection	15–26 year old women	HPV quadravalent vaccine months 0, 2, and 6 (CIII)
Bacteria	Neutropenia	Granulocyte colony-stimulating factor (G-CSF), 5–10 mcg/kg subcutaneously once daily for 2–4 weeks; or granulocyte-macrophage colony-stimulating factor (GM-CSF), 250 mcg/m² subcutaneously for 2–4 weeks (CII)
Histoplasma capsulatum	CD4+ count <150/mm³, endemic geographic area and high risk for exposures	Itraconazole 100–200 mg orally once daily (CI)

See Table 134–4 for levels of evidence-based recommendations.
From reference 53.

extensive as in the published guidelines, which include multiple additional alternatives and cover other less common OIs.[53] The following brief discussion of PCP provides an overview of the epidemiology, diagnosis, clinical manifestations, and results of treatment and serves as an illustration for the principles discussed earlier.

PNEUMOCYSTIS CARINII (PNEUMOCYSTIS JIROVECI) PNEUMONIA

PCP has been and continues to be the most common life-threatening OI in patients with AIDS.[77] *P. jiroveci* was formerly named *P carinii*; the name change was made to distinguish the organism that infects humans (*P. jiroveci*) from the strain that infects rodents (*P carinii*). The acronym PCP is still used today. Early in the AIDS epidemic 80% of patients experienced PCP at some point during their lifetime.[53,78] Although the incidence of PCP has fallen substantially since the advent of ART and effective prophylaxis for PCP, it still occurs in persons unaware of their HIV infection, and breakthrough PCP can occur in those with variable adherence to ART and/or prophylaxis.[53]

P. jiroveci is a fungus that has protozoan characteristics as well.[77,78] Exposure to *P. jiroveci* is widespread; two thirds of the population has developed serum antibodies by age 2 to 4 years.[53] The organism appears to reside without consequence in humans unless the host becomes immunologically impaired.[79] Disease associated with immunosuppression probably occurs from both new acquisition and reactivation. Ninety percent of PCP cases in AIDS patients occurred in those with CD4 counts less than 200 cells/mm³.[53] Other risk factors include oral thrush, recurrent bacterial pneumonia, unintentional weight loss, and high plasma HIV RNA. Past episodes of PCP increase risk for future episodes, which provides the basis for secondary chemoprophylaxis, as described below.[53]

The presentation of PCP in AIDS often is insidious.[53,77] Characteristic symptoms include fever and dyspnea. Clinical signs are tachypnea with or without rales or rhonchi and a nonproductive or mildly productive cough occurring over a period of weeks, although more fulminant presentations can occur. Chest radiographs may show florid or subtle infiltrates but occasionally are normal. Infiltrates usually are interstitial and bilateral, however. Arterial blood gases may show minimal hypoxia (Pao_2 80–95 mm Hg) but in more advanced disease may be markedly abnormal. The diagnosis of PCP usually is made by identification of the organism in induced sputum or in specimens obtained from bronchoalveolar

lavage. Less commonly, transbronchial or open lung biopsy is used to locate the organism. Diagnostic PCR tests are available in some institutions.[77]

Untreated PCP has a mortality rate of nearly 100%. Several potential treatments are available for PCP, but the treatment of choice is trimethoprim–sulfamethoxazole (or cotrimoxazole), which is associated with a response rate of 60% to 100%.[53] Parenteral pentamidine is equally efficacious but significantly more toxic. Trimethoprim–sulfamethoxazole is also the regimen of choice for primary and secondary prophylaxis of PCP in patients with and without HIV.[53,77]

When used for treatment of PCP, the dose of trimethoprim–sulfamethoxazole is 15 to 20 mg/kg/day (based on the trimethoprim component) as three to four divided doses.[53,77] Treatment duration typically is 21 days but also must be based on clinical response. Trimethoprim–sulfamethoxazole usually is initiated by the intravenous route, although oral therapy may suffice in mildly ill and reliable outpatients or for completion of a course of therapy after a response has been achieved with intravenous administration. Patients with moderate to severe PCP should be treated with corticosteroids as soon as possible after starting PCP therapy and certainly within 72 hours, in order to blunt the deterioration seen just after initiation of PCP therapy. Alternative regimens include pentamadine for moderate to severe disease and dapsone with trimethoprim, primaquine with clindamycin, and atovaquone for mild to moderate PCP.[53] Early initiation of ART is also generally recommended as long as there are no contraindications.[76]

Adverse reactions to trimethoprim–sulfamethoxazole and pentamidine are common, occurring in 20% to 85% of patients in this setting.[53] The more common adverse reactions seen with trimethoprim–sulfamethoxazole are rash (including Stevens-Johnson syndrome), fever, leukopenia, elevated serum transaminase levels, and thrombocytopenia. The incidence of these adverse reactions is higher in HIV-infected individuals than in those not infected with HIV.[80] Mild rashes should be watched closely for progression to more severe reactions but are not an absolute contraindication to continuing therapy.[53] This highlights the need for thoughtful consideration of ART components because of overlapping toxicities with some antiretrovirals such as abacavir and nevirapine, which also are associated with rash and hypersensitivity, including life-threatening cases. For pentamidine, side effects are pronounced and include hypotension, tachycardia, nausea, vomiting, severe hypoglycemia or hyperglycemia, pancreatitis, irreversible diabetes mellitus, elevated serum transaminase levels, nephrotoxicity, leukopenia, and cardiac arrhythmias. Some of these reactions appear to be related to the infusion rate (e.g., hypotension and tachycardia) and can be minimized by infusing pentamidine over 1 hour or more.[78] Dosage modification or pharmacokinetic monitoring can reduce the toxicity of both pentamidine and trimethoprim–sulfamethoxazole.[81] Dose reduction of pentamidine from 4 to 3 mg/kg/day appears to be successful in minimizing further rises in serum creatinine levels.[78] Maintenance of serum trimethoprim concentrations between 5 and 8 mcg/mL may help to prevent severe myelosuppression.[81] Early addition of adjunctive corticosteroid therapy to anti-PCP regimens decreases the risk of respiratory failure and improves survival in patients with AIDS and moderate to severe PCP (Pao_2 ≤70 mm Hg or alveolar-arterial gradient ≥35 mm Hg).[53,77] The adverse effects associated with corticosteroid therapy in these patients were minimal, primarily an increased incidence of herpetic lesions, although some concerns exist about the potential for reactivation of tuberculosis or cytomegalovirus and/or long-term effects on bones.[78,82]

Prevention of PCP is clearly a preferable treatment strategy. Primary prophylaxis is recommended for any HIV-infected person who has a CD4 lymphocyte count less than 200 cells/mm^3 (or CD4 percentage of total lymphocytes <14%) or a history of oropharyngeal candidiasis.[53,77] Secondary PCP prophylaxis is recommended for all HIV-infected individuals who have had a previous episode of PCP.

Trimethoprim–sulfamethoxazole is the most effective and least expensive agent and is the preferred therapy for both primary and secondary prophylaxis of PCP in adults and adolescents.[53,77] It also appears to confer cross-protection against toxoplasmosis and many bacterial infections. The recommended dose in adults and adolescents is one double-strength tablet daily, although other regimens, such as one double-strength tablet thrice weekly or one single-strength tablet daily and gradual dose escalation using liquid trimethoprim–sulfamethoxazole, have been used in an attempt to reduce the incidence of adverse reactions and improve compliance. Alternative prophylactic regimens are available if trimethoprim–sulfamethoxazole cannot be tolerated.

In the ART era, the profound reduction in HIV replication and restoration in CD4 cell count to levels rarely associated with the development of OIs provides a basis for the discontinuation of primary and secondary prophylaxis.[53] For PCP, primary prophylaxis should be discontinued in patients receiving and responding to ART who have a CD4 cell count greater than 200 cells/mm^3 sustained for at least 3 months, but should be reinstated if the CD4 count drops to less than 200 cells/mm^3. The same criteria apply for both discontinuation and reinitiation of secondary prophylaxis of PCP. However, continued secondary prophylaxis should be considered when the original PCP episode occurred at a CD4 count greater than 200 cells/mm^3.[53]

In summary, comprehensive recommendations are available for management of PCP and other OIs in the context of HIV infection including prevention and treatment.[53] Readers are advised that data continue to emerge on new OI therapies, the safety of stopping primary and secondary prophylaxis, as well as criteria for when to restart secondary prophylaxes. The most current guidelines always should be consulted. Similar OI guidelines have been developed and are updated regularly that are specific to children.[34]

COMPLICATIONS IN THE ART ERA

⓾ As with any medication, adverse reactions occur with antiretroviral agents that can range from life-threatening to minor intolerances. Characteristic side effects for each antiretroviral agent are listed in Table 134–5. A comprehensive discussion of all the adverse effects during antiretroviral therapy is beyond the scope of this chapter, but can be found in various other sources.[23,44,45] The purpose of this section is to highlight certain medical issues that have emerged in the ART era as HIV-infected patients live longer and are exposed to antiretroviral drugs for many years.

A broad spectrum of complications usually associated with aging appear to occur earlier in HIV-infected patients in the ART era.[73] These complications include osteoporosis and osteopenia, renal insufficiency, metabolic syndrome, neurocognitive decline, atherosclerotic disease, frailty, and malignancy. The cause of the early manifestation of these complications is not entirely clear, but evidence suggests that immune-dysregulation (e.g., a state of persistent heightened cellular activation) and viral replication play a role, as well as adverse events from antiretroviral medications.[73,82]

While contemporary antiretroviral therapy has reduced the incidence of some HIV-related cancers such as Kaposi sarcoma and non-Hodgkin lymphoma, other non-AIDS–related malignancies are beginning to plague HIV-infected individuals at significantly elevated rates such as Hodgkin lymphoma and anal-, lung-, skin- and hepato-carcinoma.[83] Part of, but not all, this increased risk in HIV-infected patients may be attributed to elevated exposures to human papillomavirus (anal cancer), smoking (lung carcinoma), and chronic hepatitis B and/or C co-infection (liver cancer). Some

concern has been raised that antiretroviral drugs may contribute directly to these increased cancer rates, as some agents have caused cancers in laboratory animals as well as genotoxicity in vitro.[11] However, studies have shown similar cancer rates in organ transplant recipients with medication-induced immunosuppression, which suggests that it is the impairment to the immune system associated with HIV infection that is driving these higher cancer rates.[84] While the approach to treatment of malignancies in HIV-infected patients is similar to that in non-HIV–infected patients, treatment is complicated by drug–drug interactions that may exist between the antiretrovirals and the oncolytics.[83]

Antiretroviral drugs may contribute to several complications. Tenofovir has been associated with renal proximal tubulopathy (including rare cases of Fanconi syndrome and renal failure) as well as osteopenia.[85] Protease inhibitors and zidovudine-lamivudine have also been associated with osteopenia, although the precise mechanism for these effects is not clear.[86,87] Relationships exist between protease inhibitors, efavirenz, and the thymidine analog NRTIs and dyslipidemia (increased triglycerides and low-density lipoproteins [LDLs] and decreased high-density lipoproteins), abnormal glucose homeostasis (insulin resistance and impaired glucose tolerance), body fat abnormalities (lipoatrophy of the face and extremities and central lipoaccumulation), and lactic acidosis with hepatosteatosis (for all the NRTIs).[88,89] These metabolic abnormalities often occur in combination. Notably, some of the same abnormalities are also associated with the HIV infection itself, such as hypertriglyceridemia and insulin resistance.[88] Distinguishing the contribution of disease versus drug and ascertaining whether one abnormality precipitates the development of other abnormalities is difficult.[89,90] Various mechanistic hypotheses have been put forward, including NRTI-induced mitochondrial toxicity, and PI/NNRTI interactions with various cellular processes, such as glucose uptake, altered apolipoprotein degradation or synthesis, adipocyte differentiation, and lipolysis.[88,90] Some agents within these classes are less associated with these complications, including atazanavir for the PIs, nevirapine for NNRTIs, and tenofovir and abacavir for the NRTIs.[88] Early evidence also suggests that raltegravir and maraviroc are less associated with metabolic complications as well.[62,91]

Metabolic complications create several challenges and concerns. First, the metabolic abnormalities may increase the risk of adverse cardiovascular events, and some evidence gives credence to this concern.[88] A large observational prospective cohort study of 23,468 HIV-infected patients applied the Framingham cardiovascular risk algorithm and compared the estimated cardiovascular event rate with the actual event rate.[92] The algorithm takes into account known risk factors, many of which are associated with ART, such as diabetes and dyslipidemia as well as sex, age, smoking, and blood pressure. The estimated event rate paralleled the actual event rate, and both increased with years on ART. This finding suggests that increased cardiovascular risk can be explained by conventional risk factors, which are aggravated by ART. Therefore, the metabolic abnormalities precipitated by ART and HIV should be treated as cardiovascular disease risk factors and may warrant medical intervention. Finally, some observational studies have found an association between myocardial infarction and abacavir and didanosine use.[93] However, these associations have not been duplicated in other datasets, so these findings are tentative at this time.[94]

A second concern and challenge is how to manage the changes in body fat distribution, which can be disfiguring and upsetting to patients.[90] Some strategies have led to a mild return of subcutaneous fat for those with severe peripheral lipoatrophy. Controlled trials of antiretroviral substitution have demonstrated that patients randomized to switch away from stavudine to either abacavir or tenofovir have had small gains in subcutaneous fat.[95] Small controlled studies have demonstrated modest but inconsistent gains in subcutaneous fat with thiazolidinedione therapy.[96] Central fat accumulation is difficult to treat. Metformin reduces central fat accumulation, but lean body mass and subcutaneous fat may exhibit unwanted declines.[96] Lifestyle changes, such as reducing calorie intake and increasing aerobic exercise, may reduce central fat. Unfortunately, both lipoatrophy and fat accumulation eventually may lead to reconstructive surgery strategies in severe or refractory cases. Perhaps the best management of body fat changes is prevention through initiation of regimens less likely to cause such changes (see current recommendations for initial therapy).[23]

ART-associated hyperlipidemia can create several therapeutic challenges. Antiretroviral substitution studies have shown lipid improvements after switching away from PIs to either NNRTIs or atazanavir, but direct pharmacologic intervention may be required.[96] Elevated LDL may respond to β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor (statin) therapy. However, serious concerns exist regarding drug–drug interactions between PIs and statins, including lovastatin and simvastatin.[23,96] The plasma area under the concentration time curve of these statins can be increased >10-fold and may increase the risk for rhabdomyolysis. Generally, fluvastatin, pravastatin, atorvastatin, or rosuvastatin are recommended for ART-associated LDL elevations. Guidelines generally recommend starting with low doses with careful monitoring. Other HIV-specific recommendations exist for lifestyle modifications, and the use of fibrates, niacin, ezetimibe, and/or fish oil for isolated hypertriglyceridemia.[23] Current guidelines should always be consulted, as new information regarding the special concerns and challenges associated with HIV associated metabolic abnormalities continue to accrue.[88,96]

Many HIV-infected patients are co-infected with hepatitis C (HCV), which poses another challenge in the ART-era. HIV–HCV coinfection is common because of the shared blood-borne route of transmission.[97,98] Approximately 30% of HIV-infected patients in the United States have HIV–HCV (approximately 300,000 individuals). Up to 90% of injection-drug users and 90% of hemophiliacs with HIV are coinfected with HCV.[97]

Medical management of HIV–HCV-infected patients is complicated. First, HIV worsens the prognosis of HCV by reducing the chance of HCV clearance and accelerating HCV progression. After acute HCV infection, approximately 20% of patients without HIV will clear HCV compared with only 5% to 10% of those who also have HIV. With chronic HCV infection, progression to fibrosis, cirrhosis, and liver failure is several-fold faster in HIV–HCV patients versus HCV-monoinfected patients.[98] Whether HCV alters HIV disease is unclear, as the evidence to date is mixed. However, it is clear that end-stage liver disease from HCV has become an important cause of morbidity and death in HIV–HCV-infected patients.[23]

Randomized controlled trials have demonstrated lower response rates to standard-of-care HCV therapy (ribavirin and pegylated interferon-α) in HIV–HCV-infected patients compared with similar studies in HCV-monoinfected patients.[97,98] HIV–HCV patients in these studies had high levels of CD4 cells (average ~500 cells/mm^3) and either were taking ART or had stable HIV disease. Sustained virologic responses for HCV were only 27% to 44% overall (14%–29% for HCV genotype 1), which compares poorly with response rates in HCV-monoinfected patients (>50% overall and >40% for HCV genotype 1). In HCV monoinfection, genotype 2 and 3 can be treated for 24 weeks, whereas HIV–HCV patients may need 48 weeks of treatment for the same genotypes.[98] Generally, HIV-induced immunologic defects may worsen HCV disease and response, but the precise underlying mechanism(s) of this attenuated HCV response in HIV–HCV patients has not been fully elucidated.[97,98]

Another challenge in HIV–HCV patients is the potential for liver toxicity to ART. Coinfected patients have several-fold higher risk of ART-associated transaminase elevations versus patients infected with HIV but not HCV.[97,98] Nevirapine and full-dose ritonavir appear to carry the highest risk of transaminase elevations, whereas stavudine has been linked with steatosis. Ritonavir-boosted PIs generally do not carry the same elevated risk as full-dose ritonavir with the exception of tipranavir-ritonavir or darunavir-ritonavir, which are associated with risk of clinical hepatitis and hepatic decompensation in those with HCV or hepatitis B infections. Liver function must be monitored with extra vigilance if tipranavir or darunavir are used in this population.[23] Stavudine and didanosine (also see below) are generally not recommended in combination with HCV therapy owing to risk of mitochondrial toxicity.[97,98] Other than these examples, the general threat of major liver toxicity is low overall, and this concern should not dissuade the use of ART in HIV–HCV-coinfected persons given the known benefits of therapy.[97,98]

Finally, two potentially dangerous drug–drug interactions exist between ART and HCV therapies. Didanosine should not be used with HCV therapy because of increased risk for pancreatitis and/or lactic acidosis.[97,98] The mechanism for this increase risk is not entirely clear, but may involve an intracellular interaction. Ribavirin inhibits inosine 5′-monophosphate dehydrogenase in vitro, which increases the phosphate donor pool available such that higher intracellular levels of dideoxyadenosine triphosphate (the active anabolite of didanosine) are produced with potentially more mitochondrial toxicity.[99] The other potentially dangerous interaction is severe anemia when zidovudine is used with ribavirin and interferon.[97,98] This appears to be a pharmacodynamic interaction, as zidovudine reduces red blood cell output and ribavirin causes hemolysis. At this time, zidovudine is not contraindicated with ribavirin and interferon, but close hematologic monitoring is needed.[97,98] It is likely that the list of drug–drug interactions among ART and HCV therapies will lengthen as therapeutic options for HCV expand.

As with the many other special circumstances and considerations that apply in the management of HIV-infected patients discussed in this chapter, specific guidelines have been established for managing HCV in HIV–HCV-coinfected patients, including recommendations for managing ART-associated liver toxicity.[23,100] The most current recommendations should always be consulted, as new knowledge and treatment strategies accrue continuously.

CONCLUSIONS

Irrefutable progress has been made in the management of HIV. Disease progression can be delayed, survival can be prolonged, and the risk of maternal-to-fetal HIV transmission can be reduced substantially. However, a cure and an effective vaccine remain elusive. Twenty-four distinct antiretroviral agents are available now for clinical use, and additional compounds will follow. There continues to be progress in our understanding of the virologic and immunologic processes associated with HIV infection and the clinical pharmacology of anti-HIV compounds, but deficits remain. Particular issues include the ever-present need for simpler and more tolerable and potent regimens, strategies for drug-resistant viral isolates, and better understanding of the inexorably progressive nature of HIV infection in some patients despite antiretroviral therapy. The medical management of OIs associated with HIV disease has changed dramatically since the recognition of AIDS early in the 1980s and changes continue today. The approach to PCP is illustrative. Chronologic landmarks in the evolution of PCP management include treatment of only established PCP disease to treatment in which primary and secondary prophylaxis based on CD4 lymphocyte count are standards of care, and finally to treatment where prophylaxis should be discontinued with sustained CD4 recovery on ART. Such evolution reflects progress in both understanding the risk factors for OIs and pharmacologic therapy. Collectively, three important general lessons have been learned from the treatment of HIV and associated OIs: the need for prospective immunologic and virologic monitoring and early recognition of HIV infection, the use of potent combinations of antiretroviral agents to maximally inhibit viral replication and restore immune function, and the primary and secondary prophylaxis of OIs. Observance of these principles, coupled with carefully controlled investigations of novel agents and therapeutic strategies, will continue to offer definite benefit and improve the quality and duration of life for HIV-infected individuals and yield an advantage over this pernicious virus that causes AIDS.

SECTION 17
ONCOLOGIC DISORDERS

CHAPTER 135

Cancer Treatment and Chemotherapy

PATRICK J. MEDINA AND STACY S. SHORD

KEY CONCEPTS

1. Carcinogenesis is a multistep process that includes initiation, promotion, conversion, and progression. The growth of both normal and cancerous cells is genetically controlled by the balance or imbalance of oncogene, proto-oncogene, and tumor suppressor gene protein products. Multiple genetic mutations are required to convert normal cells to cancerous cells. Apoptosis and cellular senescence (aging) are normal mechanisms for cell death.

2. Because patients with clinically evident metastatic cancer can rarely be cured, early detection is critical. Screening programs are designed to detect cancers in asymptomatic people who are at risk of a specific type of cancer. Knowing the early warning signs of cancer is also important in early detection, when cancers are most likely to be localized.

3. Treatment for cancer should not begin until the presence of cancer is confirmed by a tissue (e.g., histologic) diagnosis. Clinical cancer staging provides prognostic information, and in conjunction with the patient's treatment goals, guides the selection of cancer treatment. The goals of cancer treatment include cure, prolongation of life, and relief of symptoms. Surgery and radiation therapy provide the best chance of cure for patients with localized cancers, but systemic treatment methods are required for disseminated cancers.

4. Adjuvant therapy is systemic therapy that is administered to treat any existing micrometastases remaining after surgical excision of localized disease. Because adjuvant therapy is given to patients with no remaining clinical evidence of cancer, the benefit of the treatment cannot be proven for an individual patient, but only for patient populations. Treatment decisions are based largely on an assessment of the presence of risk factors in an individual patient and the patient's estimated risk for cancer recurrence. The effectiveness of adjuvant therapies is measured by the relative and absolute reduction in the risk of recurrence.

5. Traditional chemotherapy agents target rapidly proliferating cells. Agents can be either "cell-cycle phase-specific," targeting one specific phase of the cell cycle, or "cell-cycle phase-nonspecific," targeting all proliferating cells regardless of their place in the cell cycle. Cell-cycle phase-specific agents are generally given more frequently or as continuous infusions while cell-cycle phase-nonspecific agents are usually given as a single dose.

6. Monoclonal antibodies recognize an antigen that is expressed preferentially on cancer cells or target growth factors responsible for cancer growth. These agents can vary in the amount of foreign component that can be used to predict tolerability of the agents. Monoclonal antibodies that target cellular antigens induce cell death by a variety of mechanisms that involve the host immune system. These agents can also be used to deliver drugs or radioisotopes to the antigen-expressing cells.

7. The HER (human epidermal growth factor receptor) family contains four known receptor subtypes that regulate cell proliferation pathways through signal transduction. The HER family is dysregulated in many common tumors. Several agents have been developed to prevent signal transduction through this pathway. Monoclonal antibodies, which competitively bind to extracellular receptors, and small molecular inhibitors, which target intracellular signal transduction pathways, are commercially available for several malignancies.

8. Tumors must develop new blood vessels through the process of angiogenesis in order to grow. This process, regulated by proangiogenic and antiangiogenic factors, becomes dysregulated in several malignancies and can lead to tumor growth, invasion, and metastasis. New anticancer agents can target this process and decrease tumor growth.

9. Understanding the mechanism of chemotherapy toxicities can lead to more effective prevention and treatment of these toxicities. Prospective dose modification of some chemotherapeutic agents and targeted therapies are essential in patients

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

with impaired renal or hepatic function, to reduce the risk of severe toxicities. Identification of genetic variations that affect activation and metabolism may permit the development of individualized therapy that optimize effectiveness and minimize toxicity.

10 Myelosuppression is the acute dose-limiting toxicity for most nonspecific chemotherapeutic agents. Anemia can cause fatigue in cancer patients, whereas risk of infection in patients is related to the depth and duration of neutropenia. Unexplained fever in neutropenic patients requires prompt initiation of empiric antibiotic therapy. Colony-stimulating factors are available to improve fatigue in patients with anemia and reduce the risk of febrile neutropenia. Evidence-based clinical guidelines should direct the use of these supportive care measures.

Cancer is a group of more than 100 different diseases that are characterized by uncontrolled cellular growth, local tissue invasion, and distant metastases.[1] It is now the leading cause of mortality in Americans younger than age 85 years. About 1.5 million cases of cancer will be diagnosed in 2009, and cancer will claim an estimated 562,340 lives in the United States.[2] Figure 135–1 illustrates the estimated incidence of common cancers and cancer-related deaths. The four most common cancers are prostate, breast, lung, and colorectal cancer. The most common cause of cancer-related deaths in the United States is lung cancer, which accounts for about 160,000 deaths each year. These cancers are discussed in further detail in the chapters that follow.

The roles of healthcare professionals in the management of cancer patients can be very diverse. Thorough knowledge of anticancer drug pharmacology and pharmacokinetics is essential to prevent and manage drug-induced toxicities. Supportive care issues, such as nutritional support, pain management, infection, and nausea and vomiting, require application of clinical, pharmacologic, and economic principles. Provision of drug information to other healthcare professionals and to patients and their families is another critical role. Experienced healthcare professionals are able to fulfill these roles and to make valuable contributions to patient care in the oncology setting.

Estimated new cases*

	Males			Females	
Prostate	217,730	28%		Breast	207,090	28%
Lung & bronchus	116,750	15%		Lung & bronchus	105,770	14%
Colon & rectum	72,090	9%		Colon & rectum	70,480	10%
Urinary bladder	52,760	7%		Uterine corpus	43,470	6%
Melanoma of the skin	38,870	5%		Thyroid	33,930	5%
Non-Hodgkin lymphoma	35,380	4%		Non-Hodgkin lymphoma	30,160	4%

This chapter introduces the basic concepts of carcinogenesis, tumor growth, and cancer treatment, provides general information on the pharmacology and clinical use of the antineoplastic agents, and presents an overview of supportive care issues in the oncology patient.

ETIOLOGY OF CANCER

CARCINOGENESIS

1 The mechanisms by which cancers occur are incompletely understood. A cancer, or neoplasm, is thought to develop from a cell in which the normal mechanisms for control of growth and proliferation are altered. Current evidence supports the concept of carcinogenesis as a multistage process that is genetically regulated.[3–6] The first step in this process is *initiation*, which requires exposure of normal cells to carcinogenic substances. These carcinogens produce genetic damage that, if not repaired, results in irreversible cellular mutations. This mutated cell has an altered response to its environment and a selective growth advantage, giving it the potential to develop into a clonal population of neoplastic cells. During the second phase, known as *promotion*, carcinogens or other factors alter the environment to favor growth of the mutated cell population over normal cells. The primary difference between initiation and promotion is that promotion is a reversible process. Because it is reversible, the promotion phase may be the target of future chemoprevention strategies, including changes in lifestyle and diet. At some point, however, the mutated cell becomes cancerous (*conversion* or *transformation*). Depending on the type of cancer, 5 to 20 years may elapse between the carcinogenic phases and the development of a clinically detectable cancer. The final stage of neoplastic growth, called *progression*, involves further genetic changes leading to increased cell proliferation. The critical elements of this phase include tumor invasion into local tissues and the development of metastases.

Substances that may act as carcinogens or initiators include chemical, physical, and biologic agents.[5] Exposure to chemicals may occur by virtue of occupational and environmental means, as well as lifestyle habits. The association of aniline dye exposure and bladder cancer is one such example. Benzene is known to cause leukemia. Some drugs and hormones used for therapeutic purposes are also classified as carcinogenic chemicals (Table 135–1). Physical agents that act as carcinogens include ionizing radiation and ultraviolet light. These types of radiation induce mutations by forming free radicals that damage DNA and other cellular components. Viruses are biologic agents that are associated with certain cancers. The Epstein-Barr virus is believed to be an important factor in the initiation of Burkitt lymphoma. Likewise, infection with human papilloma virus is known to be a major cause of cervical cancer. All the previously mentioned carcinogens, as well as age, gender, diet, growth factors, and chronic irritation, are among the factors considered to be promoters of carcinogenesis.

TABLE 135-1 Selected Drugs and Hormones Known to Cause Cancer in Humans

Drug or Hormone	Type of Cancer Caused
Alkylating agents (e.g., chlorambucil, mechlorethamine, melphalan, nitrosoureas)	Leukemia
Anabolic steroids	Liver
Analgesics containing phenacetin	Renal, urinary bladder
Anthracyclines (e.g., doxorubicin)	Leukemia
Antiestrogens (tamoxifen)	Endometrium
Coal tars (topical)	Skin
Estrogens	
Nonsteroidal (diethylstilbestrol)	Vagina/cervix, endometrium, breast, testes
Steroidal (estrogen replacement therapy, oral contraceptives)	Endometrium, breast, liver
Epipodophyllotoxins (etoposide, teniposide)	Leukemia
Immunosuppressive drugs (cyclosporine, azathioprine)	Lymphoma, skin
Oxazaphosphorines (cyclophosphamide, ifosfamide)	Urinary bladder, leukemia

GENETIC AND MOLECULAR BASIS OF CANCER

1 In recent years there has been marked progress in our understanding of the genetic changes that lead to the development of cancer, largely because of improvements in research techniques and new genomic information.[3,5–7] Two major classes of genes are involved in carcinogenesis: oncogenes and tumor suppressor genes. Figure 135–2 illustrates the acquired capabilities of cancer cells that differ from normal cellular function.[8] Oncogenes develop from normal genes, called proto-oncogenes, and may have important roles in all phases of carcinogenesis. Proto-oncogenes are present in all cells and are essential regulators of normal cellular functions, including the cell cycle. Genetic alteration of the proto-oncogene through point mutation, chromosomal rearrangement, or gene

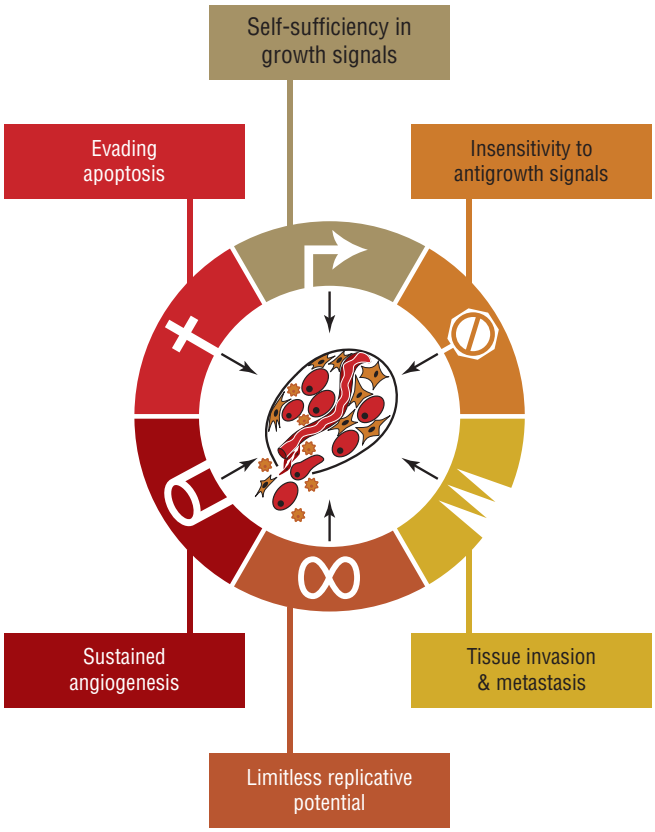

FIGURE 135-2. Functional capabilities acquired by cancer cells including angiogenesis, self-proliferation, insensitivity to antigrowth signals and limitless growth potential, metastasis; and antiapoptotic effects. It is thought that most, if not all cancer cells acquire these functions through a variety of mechanisms, including activation of oncogenes and mutations in tumor suppressor genes. *(Reprinted from Cell, Vol 100(1), Hanahan D, Weinberg RA, The Hallmarks of Cancer, pages 57–70, Copyright © 2000, with permission from Elsevier.)*

TABLE 135-2 Examples of Oncogenes and Tumor Suppressor Genes

Gene	Function	Associated Human Cancer
Oncogenes		
Genes for growth factors or their receptors		
EGFR or Erb-B1	Codes for epidermal growth factor (EGFR) receptor	Glioblastoma, breast, head and neck, and colon cancers
HER-2/neu or Erb-B2	Codes for a growth factor receptor	Breast, salivary gland, prostate, bladder, and ovarian cancers
RET	Codes for a growth factor receptor	Thyroid cancer
Genes for cytoplasmic relays in stimulatory signaling pathways		
K-RAS and N-RAS	Code for guanine nucleotide-proteins with GTPase activity	Lung, ovarian, colon, pancreatic binding cancers Neuroblastoma, acute leukemia
Genes for transcription factors that activate growth-promoting genes		
c-MYC		Leukemia and breast, colon, gastric, and lung cancers
N-MYC		Neuroblastoma, small cell lung cancer, and glioblastoma
Genes for cytoplasmic kinases		
BCR-ABL	Codes for a nonreceptor tyrosine kinase	Chronic myelogenous leukemia
Genes for other molecules		
BCL-2	Codes for a protein that blocks apoptosis	Indolent B-cell lymphomas
BCL-1 or PRAD1	Codes for cyclin D_1, a cell-cycle clock stimulator	Breast, head, and neck cancers
MDM2	Protein antagonist of p53 tumor suppressor protein	Sarcomas
Tumor-suppressor genes		
Genes for proteins in the cytoplasm		
APC	Step in a signaling pathway	Colon and gastric cancer
NF-1	Codes for a protein that inhibits the stimulatory Ras protein	Neurofibroma, leukemia, and pheochromocytoma
NF-2	Codes for a protein that inhibits the stimulatory Ras protein	Meningioma, ependymoma, and schwannoma
Genes for proteins in the nucleus		
MTS1	Codes for p16 protein, a cyclin-dependent kinase inhibitor	Involved in a wide range of cancers
RB1	Codes for the pRB protein, a master brake of the cell cycle	Retinoblastoma, osteosarcoma, and bladder, small cell lung, prostate, and breast cancers
p53	Codes for the p53 protein, which can halt cell division and induce apoptosis	Involved in a wide range of cancers
Genes for protein whose cellular location is unclear		
BRCA1	DNA repair, transcriptional regulation	Breast and ovarian cancers
BRCA2	DNA repair	Breast cancer
VHL	Regulator of protein stability	Renal cell cancer
MSH2, MLH1, PMS1, PMS2, MSH6	DNA mismatch repair enzymes	Hereditary nonpolyposis colorectal cancer

Data from Liotta et al,[3] Cotran et al,[6] and Weinberg.[7]

amplification activates the oncogene. These genetic alterations may be caused by carcinogenic agents such as radiation, chemicals, or viruses (somatic mutations), or they may be inherited (germ-line mutations). Once activated, the oncogene produces either excessive amounts of the normal gene product or an abnormal gene product. The result is dysregulation of normal cell growth and proliferation, which imparts a distinct growth advantage to the cell and increases the probability of neoplastic transformation. An example is the human epidermal growth factor receptor (*HER*) family of oncogenes. This family of receptor tyrosine kinases contains four members: ErbB-1, also known as epidermal growth factor receptor (EGFR), HER-2, HER-3, and HER-4. When activated, these receptors mediate cell proliferation and differentiation of cells through activation of intracellular tyrosine kinase receptors and downstream signaling pathways. As an oncogene, the gene product is overexpressed or amplified, resulting in excessive cellular proliferation, metastasis, angiogenesis, and cell survival in several cancers. Table 135–2 lists examples of oncogenes by their cellular function.[9]

In contrast, tumor suppressor genes regulate and inhibit inappropriate cellular growth and proliferation.[3,6,7] Gene loss or mutation results in loss of control over normal cell growth. Two common examples of tumor suppressor genes are the retinoblastoma and *p53* genes. Mutation of *p53* is one of the most common genetic changes associated with cancer, and is estimated to occur in half of all malignancies.[7] The normal gene product of *p53* is responsible for negative regulation of the cell cycle, allowing the cell cycle to halt for repairs, corrections, and responses to other external signals. Inactivation of *p53* removes this checkpoint, allowing mutations to occur. Mutation of *p53* is linked to a variety of malignancies, including brain tumors (astrocytoma); carcinomas of the breast, colon, lung, cervix, and anus; and osteosarcoma. Another important function of *p53* may be modulation of cytotoxic drug effects. Loss of *p53* is associated with anticancer drug resistance.

Another group of genes important in carcinogenesis are the DNA repair genes. The normal function of these genes is to repair DNA that is damaged by environmental factors, or errors in DNA that occur during replication.[6] If not corrected, these errors can result in mutations that activate oncogenes or inactivate tumor suppressor genes. As more mutations in the genome occur, the risk for malignant transformation increases. The DNA repair genes have been classified as tumor suppressor genes because a loss in their function results in increased risk for carcinogenesis. Deficiencies in DNA repair genes have been discovered in familial colon cancer (hereditary nonpolyposis colon cancer) and breast cancer syndromes.

1 Oncogenes and tumor suppressor genes provide the stimulatory and inhibitory signals that ultimately regulate the cell cycle.[3,7] These signals converge on a molecular system in the nucleus known as the cell-cycle clock. The function of the clock in normal tissue is to integrate the signal input and to determine if the cell cycle should proceed. The clock is composed of a series of interacting proteins, the most important of which are cyclins and cyclin-dependent kinases. Cyclins (especially cyclin D_1) and cyclin-dependent kinases promote entry into the cell cycle and are overexpressed in several

cancers, including breast cancer. Cyclin-dependent kinase inhibitors have been identified as important negative regulators of the cell cycle.

The cell cycle proceeds from one cell division to the next. The cycle involves five phases: DNA replication (S phase), cell division (M phase), two resting phases (G_1, G_2), and a nondividing state (G_0 phase). In the first resting phase G_1, the cell grows in size and decides to commit to the cell cycle or remain in a resting state. If the cell is healthy, the cell will move into the S phase to synthesize its DNA. Next, the cell enters the second resting phase G_2, in which the cell prepares to divide. In the M phase, the cell enters mitosis and yields two daughter cells. If the cell is not healthy, the cell can stop dividing and initiate apoptosis.

Four checkpoints exist within the cell cycle, one in each phase of the cell cycle and serve as quality control checkpoints. The cell will not proceed to the next phase if all requirements for the current phase are not met. Complexes of cyclin and cyclin-dependent kinases (CDK) regulate these checkpoints. These complexes lead to the activation of other proteins that are responsible for the specific events of each phase of the cell cycle. The first checkpoint is called the restriction site. The restriction site is controlled by retinoblastoma (Rb) complexed to a transcription factor called E2F. The presence of this complex prevents cell cycle progression. A cell can proceed beyond the G_1 restriction site and continue into the S phase, when cyclin-CDK complexes phosphorylate Rb and target it for degradation. A cell may alternatively withdraw into the G_0 phase in the presence of anti-mitogenic or the absence of mitogenic factors.[10]

1 When the normal regulatory mechanisms for cellular growth fail, backup defense systems may be activated. The secondary defenses include apoptosis (programmed cell death or suicide) and cellular senescence (aging). Apoptosis is a normal mechanism of cell death required for tissue homeostasis.[3,7,11] This process is regulated by oncogenes and tumor suppressor genes and is also a mechanism of cellular death after exposure to cytotoxic agents. Overexpression of oncogenes responsible for apoptosis may produce an "immortal" cell, which has increased potential for malignancy. The *bcl-2* oncogene is an example. The most common chromosomal abnormality found in lymphoid malignancies is the t(14;18) translocation. The *bcl-2* proto-oncogene is normally located on chromosome 18. Translocation of this proto-oncogene to chromosome 14 in proximity to the immunoglobulin heavy chain gene leads to overexpression of *bcl-2*, which decreases apoptosis and confers a survival advantage to the cell. Studies show that *p53* is also a regulator of apoptosis. Loss of *p53* disrupts normal apoptotic pathways, imparting a survival advantage to the cell. Apoptosis may also play an important role as a mechanism of inherent resistance to chemotherapy.[11]

Cellular senescence is another important defense mechanism.[6,7] Laboratory studies demonstrate that once a cell population has undergone a preset number of doublings, growth stops and cells die. This is known as senescence, a process that is regulated by telomeres. Telomeres are the DNA segments or caps at the ends of chromosomes. They are responsible for protecting the end of the DNA from damage. With each replication, the length of the telomeres is shortened. After the telomeres are shortened to a critical length, senescence is triggered. In this way, telomeres tally and limit the number of cell doublings. In cancer cells, the function of telomeres is overcome by overexpression of an enzyme known as telomerase. Telomerase replaces the portion of the telomeres that is lost with each cell division, thereby avoiding senescence and permitting an infinite number of cell doublings. Telomerase is a target for anticancer drug development.

1 As information regarding the role of oncogenes and tumor suppressor genes accumulated, it became evident that a single mutation is probably insufficient to initiate cancer.[4–7] Scientists postulate that combinations of mutations are required for carcinogenesis and that each mutation is inherited by the next generation of cells. Thus, several detectable genetic mutations may be present in an established tumor. Early mutations are found in both premalignant lesions and in established tumors, whereas later mutations are found only in the established tumor. This theory of sequential genetic mutations resulting in cancer has been demonstrated in colon cancer. In colon cancer, the initial genetic mutation is believed to be loss of the adenomatous polyposis coli gene, which results in formation of a small benign polyp. Oncogenic mutation of the *ras* gene is often the next step, leading to enlargement of the polyp. Loss of function of DNA mismatch repair enzymes may occur at many points in the progression of malignant transformation. Loss of the *p53* gene and another gene, believed to be the "deleted in colorectal cancer" (DCC) gene, complete the transformation into a malignant lesion. Loss of *p53* is thought to be a late event in the development and progression of the malignancy.

Identification of genes and other proteins involved in carcinogenesis has several important clinical implications. They may be used in cancer screening to identify individuals at increased risk for cancer and are being used to design new anticancer agents and gene therapies, several of which have recently been approved for use. Specific genetic abnormalities are so commonly associated with some types of cancers that the presence of that abnormality may aid in the diagnosis of that cancer. If the presence of these genes (i.e., gene expression profile) can reliably predict the clinical course of a cancer or response to certain cancer therapies, then genetic analysis may also become an important prognostic and treatment decision tool. An example of this is overexpression of HER-2 predicting response to trastuzumab.[9]

EPIGENETICS

Epigenetics refers to changes in gene expression that occur without altering the DNA sequence.[12] The two most common mechanisms of epigenetic regulation include methylation and histone modification. DNA methylation commonly occurs at CpG dinucleotides (or islands) and is catalyzed by DNA methyltransferases (DNMT). Histones are basic proteins associated with DNA in the nucleosome. These proteins may be modified by acetylation, methylation or phosphorylation on their N-terminal tail. These modifications play a role in transcriptional regulation. For example, histone deacetylases (HDAC) repress transcription, whereas histone acetylases activate transcription. Epigenetic changes may be involved in the development of cancer by either priming the cell and making it susceptible to genetic changes associated with the development of cancer or initiating malignant transformation. As an example, hypermethylation at CpG dinucleotides found near tumor suppressor genes can switch these genes off and promote the development of cancer. New anticancer agents, classified as DNMT inhibitors or HDAC inhibitors, target these modifications.

PATHOLOGY OF CANCER

TUMOR ORIGIN

Tumors may arise from any of four basic tissue types: epithelial tissue, connective tissue (i.e., muscle, bone, and cartilage), lymphoid tissue, and nerve tissue. Although some malignant cells are atypical of their cells of origin, the involved cells usually retain enough of their parent's traits to identify their origin. Benign tumors are named by adding the suffix *-oma* to the name of the cell

TABLE 135-3 Tumor Classification by Tissue Type

Tissue of Origin	Benign	Malignant
Epithelial		
Surface epithelium	Papilloma	Carcinoma (squamous, epidermoid)
Glandular tissue	Adenoma	Adenocarcinoma
Connective tissue		
Fibrous tissue	Fibroma	Fibrosarcoma
Bone	Osteoma	Osteosarcoma
Smooth muscle	Leiomyoma	Leiomyosarcoma
Striated muscle	Rhabdomyoma	Rhabdomyosarcoma
Fat	Lipoma	Liposarcoma
Lymphoid tissue and hematopoietic cells		
Bone marrow elements		
Lymphoid tissue		Hodgkin and non-Hodgkin lymphoma
Plasma cell		Multiple myeloma
Neural tissue		
Glial tissue	"Benign" gliomas	Glioblastoma multi-forme, astrocytoma
Nerve sheath	Neurofibroma	Neurofibrosarcoma
Melanocytes	Pigmented nevus (mole)	Malignant melanoma
Mixed tumors		
Gonadal tissue	Teratoma	Teratocarcinoma

Adapted from Cotran et al.[6]

type. Hence, adenomas are benign growths of glandular origin, or growths that exhibit a glandular pattern. Table 135–3 lists common tumor nomenclature by tissue type.[6]

Some cancers are preceded by cellular changes that are abnormal, but not yet malignant. Correction of these early changes could potentially prevent the occurrence of a cancer. Precancerous lesions may be described as consisting of either hyperplastic or dysplastic cells. Hyperplasia is an increase in the number of cells in a particular tissue or organ, which results in an increased size of the organ. It should not be confused with hypertrophy, which is an increase in the size of the individual cells. Hyperplasia occurs in response to a stimulus and reverses when the stimulus is removed. Dysplasia is defined as an abnormal change in the size, shape, or organization of cells or tissues. Hyperplasia and dysplasia may precede the appearance of a cancer by several months or years.

Malignant cells are divided into those of epithelial origin or the other tissue types. Carcinomas are malignant growths arising from epithelial cells. Malignant growths of muscle or connective tissue are called sarcomas. An adenocarcinoma is a malignant tumor arising from glandular tissue. When the cancer is limited to the epithelial cells of origin, it is labeled *carcinoma in situ*. Carcinoma in situ is a preinvasive stage of malignancy, and most tumors have progressed well beyond this stage at diagnosis. Like all classification systems, there are exceptions to these rules. Malignancies of hematologic origin, such as leukemias and lymphomas, are classified separately. Leukemias and lymphomas are discussed in later chapters.

TUMOR CHARACTERISTICS

Tumors may be either benign or malignant. Benign tumors are noncancerous growths that are often encapsulated, localized, and indolent. Cells of benign tumors resemble the cells from which they developed. These masses seldom metastasize, and once removed they rarely recur. In contrast, malignant tumors invade and destroy the surrounding tissue. The cells of malignant tumors are genetically unstable, and loss of normal cell architecture results in cells that are atypical of their tissue or cell of origin. These cells lose the ability to perform their usual functions. This loss of structure and function is defined as anaplasia. In contrast to benign tumors, malignant tumors tend to metastasize, and consequently, recurrences are common after removal or destruction of the primary tumor.

INVASION AND METASTASIS

2 Metastasis is the spread of neoplastic cells from the primary tumor site to distant sites.[5,13] Despite advances in diagnostic techniques and screening for cancer, many patients have detectable metastatic disease at diagnosis. Once clinically evident distant metastases are present, cancers are seldom curable. Newly diagnosed cancer patients may also have microscopic cancer metastases (i.e., micrometastases). Although clinically undetectable, these small clusters of diseased cells must be present, because many patients subsequently relapse at distant sites despite removal of the primary tumor. Some patients with micrometastatic disease may be cured with systemic chemotherapy.

The two primary pathways of metastasis are hematogenous and lymphatic. Other less common modes of disease spread include dissemination via cerebrospinal fluid and transabdominal spread within the peritoneal cavity. Tumors are constantly shedding neoplastic cells into the systemic circulation or surrounding lymphatics. This process may begin early in the life of the tumor and often increases with time. The time course for metastasis depends largely on the biology of the tumor. Breast cancer, for example, tends to metastasize very early. Not all of the shed cancer cells, or "seeds," result in a metastatic lesion. The "seed" must first find the appropriate "soil," or an environment suitable for growth.[13] This process is illustrated in the diverse patterns of metastasis that are characteristic of individual types of cancer. An example is prostate cancer, which commonly metastasizes to bone, but rarely to the brain.

The process of invasion and metastasis involves several essential steps. After neoplastic transformation, the malignant cells and surrounding host tissue secrete substances that stimulate the formation of new blood vessels to provide oxygen and nutrients. This process is known as *angiogenesis* or *neovascularization*.[14] Tumor cells must then detach from the primary mass and invade surrounding blood and lymph vessels. The tumor cells or cell aggregates detach and embolize through these vessels, but most do not survive circulation. The disseminated cells must then attach to the vascular endothelium. The cells may proliferate within the lumen of the vessel, but most commonly extravasate into the surrounding tissue. The local microenvironment may provide growth factors that can serve as "fertilizer" to potentiate the proliferation of the metastasis. At every step of the way, the potential metastatic cell must fight the host immune system. Last, the metastasis must again initiate angiogenesis to ensure continued growth and proliferation. Because angiogenesis has been recognized as a critical element in primary tumor growth as well as metastasis, it has become a target for development of new anticancer agents, which will be described later in the chapter. Figure 135–3 summarizes the functions acquired by a cell to survive as well as mechanisms by which the cancer cell achieves this function.[8]

DIAGNOSIS AND STAGING

SCREENING

2 Because cancers are most curable with surgery or radiation before they have metastasized, early detection and treatment

A

Component	Acquired Capability	Example of Mechanism
	Self-sufficiency in growth signals	Activate H-Ras oncogene
	Insensitivity to anti-growth signals	Lose retinoblastoma suppressor
	Evading apoptosis	Produce IGF survival factors
	Limitless replicative potential	Turn on telomerase
	Sustained angiogenesis	Produce VEGF inducer
	Tissue invasion & metastasis	Inactivate E-cadherin

B

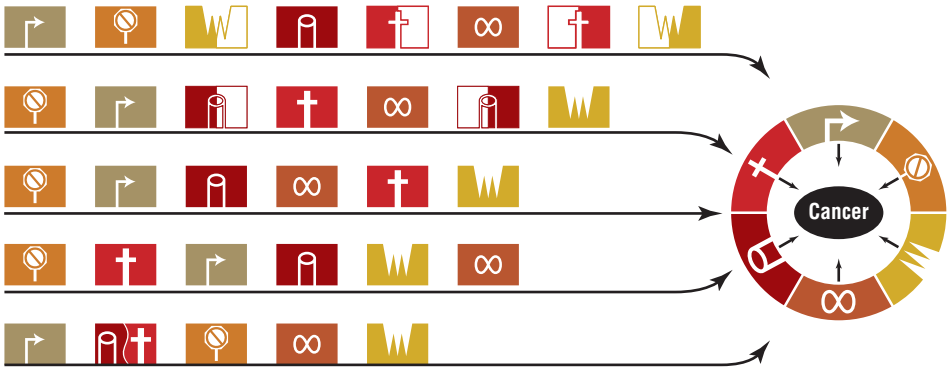

FIGURE 135-3. The mechanisms of tumorigenesis exhibited by most cancers. (IGF, insulin-like growth factor; VEGF, vascular endothelial growth factor.) *(Reprinted from Cell, Vol 100(1), Hanahan D, Weinberg RA, The Hallmarks of Cancer, pages 57–70, Copyright © 2000, with permission from Elsevier.)*

have obvious potential benefits. In addition, small tumors are more responsive to chemotherapy, as discussed previously. Early diagnosis is difficult for many cancers because they do not produce clinical signs or symptoms until they have become large or have metastasized. Cancer screening programs are designed to detect signs of cancer in people who have not yet developed symptoms from cancer. Lack of effective screening methods for some cancers and inaccessibility of some anatomic sites further complicate the process. Other limitations of screening methods include false-negatives (related to the sensitivity of the test), false-positives (related to the specificity), and overdiagnosis (true positives that will not become clinically significant). For example, most abnormal tests identified by a screening mammography are false-positives, although the specificity of this screening method exceeds 90%. Education of the public on the early warning signs of common cancers is extremely important for facilitating early detection. Effective screening procedures exist for some cancers. The Papanicolaou (Pap) smear test, for example, is an effective tool to detect cervical cancer in its early stages. The American Cancer Society has published guidelines for routine screening examinations (Table 135–4).[15]

DIAGNOSIS

The presenting signs and symptoms of cancer vary widely and depend on the type of cancer. The presentation in adults may include any of cancer's seven warning signs (Table 135–5), as well as pain or loss of appetite.[16] The warning signs of cancer in children are different, and reflect the types of tumors more common in this patient population (Table 135–6).[16] Even with increased public awareness, the fear of a cancer diagnosis can deter patients from seeking medical attention. The definitive diagnosis of cancer relies on the procurement of a sample of the tissue or cells suspected of malignancy and pathologic assessment of this sample. This sample can be obtained by numerous methods, including biopsy, exfoliative cytology, or fine-needle aspiration. A tissue diagnosis is essential, because many benign conditions can masquerade as cancer. Definitive treatment should not begin without a pathologic diagnosis.

STAGING AND WORKUP

❸ In addition to tissue diagnosis, tumors should be staged to determine the extent of disease before any definitive treatment is initiated. The process is dictated by knowledge of the biology of the tumor and by the signs and symptoms elicited in the history and physical examination. Staging provides information on prognosis and guides treatment selection. After treatment is implemented, the staging workup is usually repeated to evaluate the effectiveness of the treatment. Uniform staging criteria are important in clinical trials that evaluate cancer treatment regimens. Staging has been valuable in learning more about the biology of various tumor types. A staging workup may involve radiographs, computed tomography scans, magnetic resonance imaging, positron emission tomography scans, ultrasonograms, bone-marrow biopsies, bone scans, lumbar puncture, and a variety of laboratory tests, including appropriate tumor markers. Some cancers produce antigens or other substances that are characteristic of that particular cancer. These

TABLE 135-4 Screening Guidelines for Early Detection of Cancer in Asymptomatic People

Disease	Test or Procedure	Sex	Age (y)	Frequency
Breast cancer	Breast self-examination	F	≥20	Monthly[a]
	Clinical breast examination	F	20–39	Every 3 years
			≥40	Every year
	Mammography	F	≥40	Every year[b]
Colorectal cancer	One of the following examination schedules should be followed:			
	Fecal occult blood test (FOBT) or fecal immunochemical test (FIT)	M and F	50 and over	Every year
	Stool DNA test	M and F	≥50	Uncertain
	Flexible sigmoidoscopy	M and F	≥50	Every 5 years
	Annual FOBT or FIT and flexible sigmoidoscopy[c]	M and F	≥50	Every 5 years
	Colonoscopy	M and F	≥50	Every 10 years
	Computed tomography colonography	M and F	≥50	Every 5 years
	Double contrast barium enema	M and F	≥50	Every 5 years
Prostate cancer	Digital rectal exam and prostate-specific antigen (PSA) blood test	M	≥50	Every year[d]
Cervical cancer	Conventional pap test or liquid-based pap test	F	3 years after beginning vaginal intercourse	Every year[e]
				Every 2-3 years
Endometrial cancer	Information on risks and symptoms	F	Menopause	Once[f]
Cancer-related check-up	Health counseling and physical examination[g]	M and F	20–40	Every 3 years
			≥40	Every year

[a]Beginning in their early 20s, women should be told about the benefits and limitations of breast self-examination (BSE). The importance of prompt reporting of any new breast symptoms to a healthcare professional should be emphasized. It is acceptable for women to choose not to do BSE or to do BSE irregularly.

[b]Women at increased risk (e.g., family history, genetic tendency, or past breast cancer) should talk with their physician about benefits and limitations of starting earlier, having additional tests, or more frequent examinations.

[c]Flexible sigmoidoscopy together with FOBT or FIT is preferable to either test alone, although annual FOBT/FIT alone and flexible sigmoidoscopy every 5 years without FOBT/FIT has some benefit. People at moderate-to-high risk for colorectal cancer should discuss a different testing schedule with their physician.

[d]Healthcare providers should discuss the potential benefits and limitations of prostate cancer early detection testing with men and offer the PSA blood test and the digital rectal examination annually, beginning at age 50, to men who are at average risk of prostate cancer, and who have a life expectancy of at least 10 years.

[e]Cervical cancer screening should begin approximately 3 years after a woman begins having vaginal intercourse, but no later than age 21 years. Screening should be performed every year with conventional Pap tests or every 2 years using liquid-based Pap tests. At or after age 30 years, women who have had three normal test results in a row may get screened every 2 to 3 years with cervical cytology (either conventional or liquid-based Pap test) alone, or every 3 years with a human papillomavirus DNA test plus cervical cytology. Women aged 70+ years who have had three or more normal Pap tests and no abnormal Pap tests within the last 10 years and women who have undergone a total hysterectomy may choose to stop cervical cancer screening.

[f]Women with or at risk for hereditary nonpolyposis colon cancer should begin annual endometrial biopsy starting at age 35 years.

[g]To include examination for cancers of the mouth, thyroid, testicles, skin, lymph nodes, and ovaries, as well as health counseling about tobacco, sun exposure, diet and nutrition, risk factors, sexual practices, and environmental and occupational exposures.

From Smith et al.[15]

tumor markers are often nonspecific and may be elevated in many different cancer types, or in patients with nonmalignant diseases. As a result, tumor markers are generally more useful for monitoring response and detecting recurrence than as diagnostic tools. Examples are human chorionic gonadotropin and alfa-fetoprotein in patients with testicular cancer, or prostate-specific antigen in prostate cancer.[6]

The most commonly applied staging system for solid tumors is the TNM classification, where T = tumor, N = node, and M = metastases. A numerical value is assigned to each letter to indicate the size or extent of disease. The designated rating for tumor describes the size of the primary mass and ranges from T_1 to T_4. Carcinoma in situ is designated T_{is}. Nodes are described in terms of the extent of the spread of regional lymph nodal involvement (N_0 to N_3). Metastases are generally scored depending on their presence or absence (M_0 or M_1). To simplify the staging process, most cancers are classified according to the extent of disease by a numerical system involving stages I through IV. Stage I usually indicates localized tumor, stages II and III represent local and regional spread of disease, and stage IV denotes the presence of distant metastases. The assigned TNM rating translates into a particular stage classification. For example, T_3 N_1 M_0 describes a moderate-to-large-sized primary mass, with regional lymph node involvement and no distant metastases, and for most cancers is stage III. The criteria for classifying disease extent are quite specific for each different type of cancer.[17] For some tumors, such as prostate cancer, alternative alphabetical systems (stage A, B, C, or D) are used in clinical practice.

TABLE 135-5 Cancer's Seven Warning Signs

Change in bowel or bladder habits
A sore that does not heal
Unusual bleeding or discharge
Thickening or lump in breast or elsewhere
Indigestion or difficulty in swallowing
Obvious change in wart or mole
Nagging cough or hoarseness
If YOU have a warning signal, see your doctor!

TABLE 135-6 Cancer's Warning Signs in Children

Continued, unexplained weight loss
Headaches with vomiting in the morning
Increased swelling or persistent pain in bones or joints
Lump or mass in abdomen, neck, or elsewhere
Development of a whitish appearance in the pupil of the eye
Recurrent fevers not caused by infections
Excessive bruising or bleeding
Noticeable paleness or prolonged tiredness

TREATMENT

Modalities of Cancer Treatment

Four primary modalities are employed in the approach to cancer treatment: surgery, radiation, chemotherapy, and biologic therapy. The oldest of these is surgery, which plays a major role in the diagnosis and treatment of cancer. Surgery remains the treatment of choice for most solid tumors diagnosed in the early stages. Radiation therapy was first used for cancer treatment in the late 1800s and remains a mainstay in the management of cancer. Although very effective for treating many types of cancer, surgery and radiation are local treatments. These modalities are likely to produce a cure in patients with truly localized disease. But because most patients with cancer have micrometastatic or metastatic disease at diagnosis, localized therapies often fail to completely eliminate the cancer. In addition, systemic diseases such as leukemia cannot be treated with a localized modality. Chemotherapy and endocrine therapy access the systemic circulation and can theoretically treat the primary tumor and any metastatic disease. Biologic therapies (i.e., immunotherapy) are made from a living organism or its products and include antibodies, vaccines, growth factors and cytokines.

4 Many solid tumors or lymphomas appear to be eliminated by surgery or radiation. However, the high incidence of later recurrence implies that the primary tumor began to metastasize before it was removed. Adjuvant therapy is defined as the use of systemic agents to eradicate micrometastatic disease following localized modalities such as surgery and/or radiation. The goal of adjuvant therapy is to reduce subsequent recurrence rates and prolong long-term survival. Thus, adjuvant therapy is given to patients with potentially curable malignancies who have no clinically detectable disease after surgery or radiation. Because adjuvant therapy is given at a time when the cancer is undetectable (i.e., no measurable disease), its effectiveness cannot be measured by response rates; instead, it is evaluated by recurrence rates and survival. The value of adjuvant therapy is best established in colorectal and breast cancers. Drug therapy may also be given in the neoadjuvant or preoperative setting. The goals in this instance are to make other treatment modalities more effective by reducing tumor burden and to destroy micrometastases. It is often used to reduce the size of the primary tumor and allow for a less invasive surgical procedure. Early stage breast cancer is a good example of the use of a combined-modality approach. The primary tumor is removed surgically, and radiation therapy is delivered to the remaining breast (after lumpectomy) or to the axilla (if there is marked lymph node involvement). Adjuvant therapy is then administered to eradicate any micrometastatic disease. Neoadjuvant therapy may sometimes be administered before definitive surgery to increase the likelihood of a tumor resection compared to a mastectomy.

The management of hematological malignancies also involves the use of combined modalities, but the terminology is different. Chemotherapy that is administered to eradicate the tumor cells from the bone marrow is called induction therapy. Once a complete remission (the disappearance of all signs of the cancer) is documented, additional therapy is administered. This therapy is called post-remission or consolidation therapy and is designed to eradicate any remaining disease, similar to adjuvant therapy for solid tumors. The additional therapy may include chemotherapy, a stem cell transplant or radiation therapy. Some treatment protocols also include maintenance therapy. This therapy is given to prevent the cancer from recurring and may include a combination of anticancer agents.

When anticancer therapy is administered to patients with local or regional disease, the treatment is often administered to cure the patient and may be labeled curative therapy. However, once the cancer has metastasized to distant sites, cure is usually not possible. Anticancer therapy administered to patients with metastatic disease can often slow the progression of cancer and prolong survival by months to years. Anticancer therapy administered to patients with terminal cancer with the goal of reducing symptoms is called palliative therapy. This therapy can lead to a prolongation in overall survival.

Principles of Drug Therapy

PURPOSES OF CHEMOTHERAPY

The era of modern cancer chemotherapy was born in 1941, when Goodman and Gilman first administered nitrogen mustard to patients with lymphoma.[18] Since then, numerous anticancer agents have been developed, and a variety of chemotherapy regimens have been investigated in every type of cancer. Table 135–7 lists tumors and their responsiveness to chemotherapy.[6,19] Cancer chemotherapy may be indicated as a curative or palliative. Treatment with chemotherapeutic agents is the primary curative modality for a few diseases, including leukemias, lymphomas, choriocarcinomas, and testicular cancer. Most solid tumors are not curable with chemotherapy alone, either because of the biology of the tumor or because of advanced disease at presentation. Chemotherapy in this setting is often initiated for palliative purposes. It is often possible to decrease tumor size or to retard growth enough to reduce untoward symptoms caused by the tumor.

TABLE 135-7 The Role of Chemotherapy in the Treatment of Cancer

Chemotherapy used alone with curative intent	
Acute lymphocytic leukemia	Acute myelogenous leukemia
Burkitt lymphoma	Diffuse large B-cell lymphoma
Hodgkin lymphoma	Testicular cancer
Choriocarcinoma (gestational trophoblastic neoplasm)	
Chemotherapy used as adjuvant therapy with curative intent	
Breast cancer	Colorectal cancer
Ewing sarcoma	Osteosarcoma
Wilms tumor	Ovarian cancer
Chemotherapy used as neoadjuvant therapy	
Anal carcinoma[a]	Bladder cancer
Breast cancer (locally advanced)[a]	Cervical cancer
Esophageal cancer	Head and neck cancers[a]
Osteosarcoma[a]	Rectal cancer
Soft tissue sarcoma[a]	
Chemotherapy used to palliate symptoms in advanced disease	
Bladder cancer[a]	Brain tumors
Breast cancer[a]	Carcinoid tumors
Cervical cancer	Chronic lymphocytic leukemia
Chronic myelogenous leukemia[a]	Colorectal cancer[a]
Endometrial cancer	Esophageal cancer
Gastric cancer	Head and neck cancers
Hairy cell leukemia[a]	Kaposi sarcoma
Indolent non-Hodgkin lymphomas	Metastatic melanoma
Multiple myeloma[a]	Mycosis fungoides
Neuroblastoma[a]	Non-small-cell lung cancer
Osteosarcoma	Ovarian cancer[a]
Pancreatic cancer	Prostate cancer
Small cell lung cancer[a]	Soft-tissue sarcoma
Chemotherapy has little or no effect on palliation	
Hepatocellular cancer	Renal cell carcinoma
Thyroid cancer	

[a]Significant increase in survival is achieved.

MOLECULAR AND CELLULAR BASIS FOR DRUG THERAPY

PRINCIPLES OF TUMOR GROWTH

The study of tumor growth forms the foundation for many of the basic principles of modern cancer chemotherapy. The growth of most tumors is illustrated by the gompertzian tumor growth curve (Fig. 135–4).[6,19,20] Gompertz was an insurance actuary who described the relationship between age and expected death. This mathematical model also approximates tumor cell proliferation. In the early stages, tumor growth is exponential, which means that the tumor takes a constant amount of time to double its size. During this early phase, a large portion of the tumor cells is actively dividing. This population of cells is called the *growth fraction*. The doubling time, or time required for the tumor to double in size, is very short. Because most anticancer agents have greater effect on rapidly dividing cells, tumors are most sensitive to the effects of chemotherapy when the tumor is small and the growth fraction is high. However, as the tumor grows, the doubling time is slowed.[19,20] The growth fraction is decreased, probably owing to the tumor outgrowing its blood and nutrient supply or the inability of blood and nutrients to diffuse throughout the tumor mass. Wide variability exists in measured doubling times for different cancers. The doubling time of most solid tumors is about 2 to 3 months. However, some tumors have doubling times of only days (e.g., aggressive non-Hodgkin lymphomas) and others have even longer doubling times (e.g., some salivary gland tumors).[6]

Figure 135–4 also illustrates the impact of tumor burden. It takes about 10^9 cancer cells (1-g mass, 1 cm in diameter) for a tumor to be clinically detectable by palpation or radiography. Such a tumor has undergone about 30 doublings in cell number. It only takes 10 additional doublings for this 1 g mass to reach 1 kg in size. A tumor possessing 10^{12} cancer cells (1-kg mass) is considered lethal. Thus, a tumor is clinically undetectable for most of its life span. Tumor burden also impacts response to chemotherapy. The cell kill hypothesis states that a certain percentage of cancer cells (not a certain number of cells) will be killed with each course of chemotherapy. For example, if a tumor consists of 1,000 cancer cells and the chemotherapy regimen kills 90% of the cells, then 10% or 100 cancer cells remain. The second chemotherapy course kills another 90% of cells, and again only 10% or 10 cells remain. According to this hypothesis, the tumor burden will never reach zero. Tumors consisting of less than 10^4 cells are believed to be small enough for elimination by host factors, including immunologic mechanisms, and these factors must be in place for a cure to be possible. The limitations of this theory are that it assumes all cancers are equally responsive and that resistance to anticancer agents and metastases do not occur.[1,6,19,20]

TUMOR PROLIFERATION

Both cancer cells and normal cells reproduce in a series of steps known as the cell cycle as described earlier in the chapter. Figure 135–5 depicts the cell cycle and the phases of activity for commonly used anticancer agents.[19,20]

5 All cancer cells do not proliferate faster than normal cells; some cancer cells reproduce more rapidly while others are more indolent. Many anticancer agents target rapidly proliferating cells (both normal and cancerous cells), and these agents may act at selective or multiple sites of the cell cycle. Agents with major activity in a particular phase of the cell cycle are known as cell-cycle phase-specific agents. For example, antimetabolites exert their major effect during the S phase. Cell-cycle phase-specific agents may also be active to a lesser extent in other phases of the cycle. Cell-cycle phase-nonspecific agents are those with significant activity in multiple phases. Alkylating agents, such as nitrogen mustards, are examples of a cell-cyle non-specific agent. In many cases, the cytotoxic effects of an agent may result from interactions with other intracellular activities and are not related to specific cell-cycle events. Hormones are an example of this type of anticancer drug.

Knowledge of cell-cycle specificity has been applied to the scheduling of chemotherapy administration. By definition, cell-cycle phase-specific agents exert their major activity when cells are in a particular phase of the cell cycle. At any given time, the heterogeneous cell populations within a tumor are at various phases in the cell cycle. By giving cell-cycle phase-specific agents as a continuous infusion or in multiple repeated fractions, clinicians can theoretically target

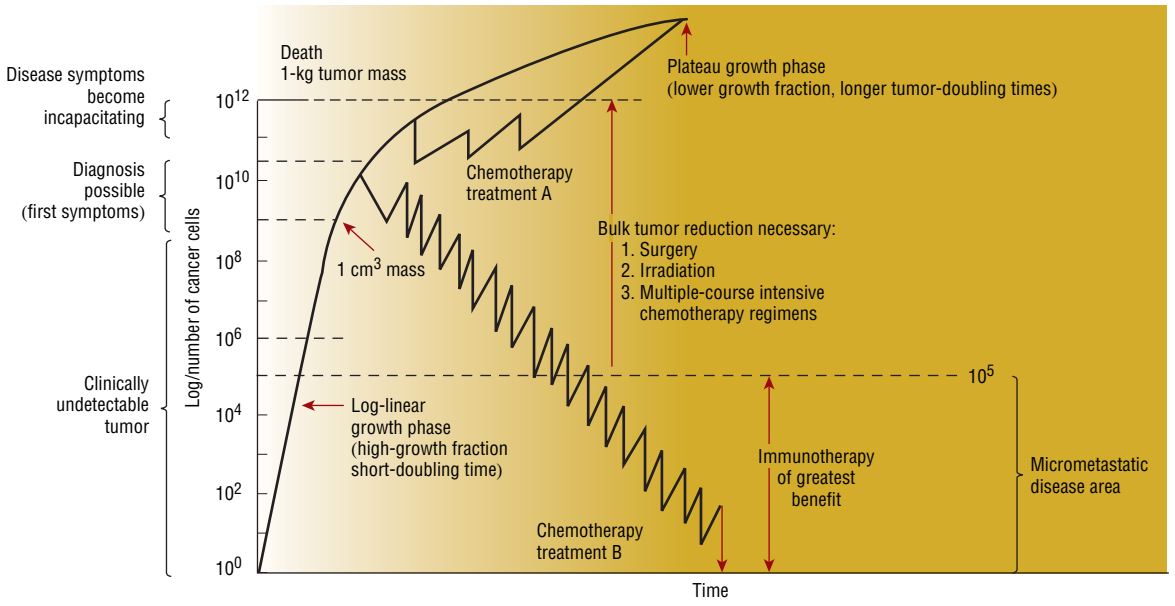

FIGURE 135-4. Gompertzian kinetics tumor-growth curve: relationship to symptoms, diagnosis, and various treatment regimens. (*Reproduced with permission from Buick.*[19])

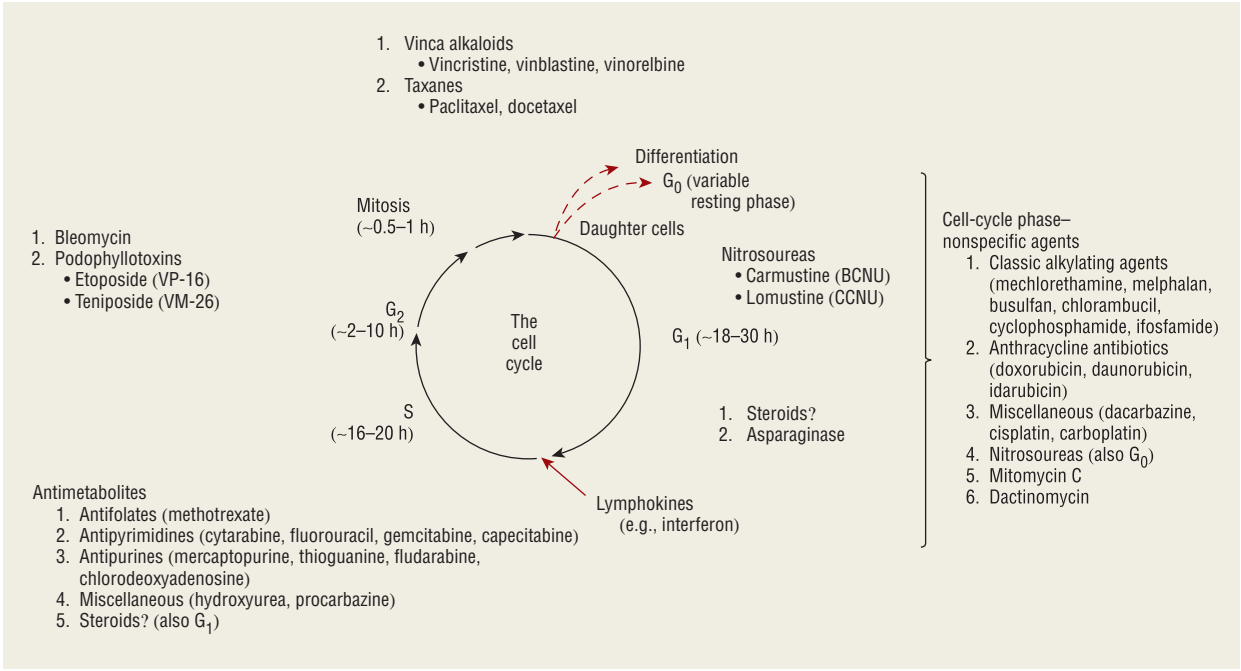

FIGURE 135-5. Cell-cycle activity for anticancer drugs. Cell-cycle phase-specific agents appear to be most active during a particular phase, but may also be active in another phase. Cell-cycle phase-nonspecific agents may have greater activity in one phase than another, but not to the degree of cell-cycle (phase)-specific agents. In many cases, it is likely that drug cytotoxicity involves multiple intracellular sites of action and may not be linked to specific cell-cycle events.

more cells as they progress into the agent's sensitive phase. Thus cell-cycle phase-specific agents are also termed *schedule dependent*. In contrast, cell-cycle phase-nonspecific agent are active in many phases, and consequently are not schedule dependent. The activity of these agents depend on the dose, and these agent are termed *dose dependent*.

MOLECULAR BIOLOGY

Because many anticancer agents interfere with the cellular synthesis of DNA, RNA, and proteins, it is important to review the basic principles of molecular biology.[3] Each normal human cell contains 46 chromosomes, which are composed of DNA (deoxyribonucleic acid). DNA carries hereditary information in units called genes. A single chromosome can contain 20,000 or more genes. Genes code for specific proteins that regulate cellular activity and inherited traits (some of which affect carcinogenesis and cancer growth, as well as the efficacy and metabolism of anticancer drugs). The genetic information is encoded in DNA by precise sequencing of subunits known as nucleotides. Each nucleotide consists of a sugar (deoxyribose), phosphoric acid, and a base. Four bases exist in DNA: adenine, thymine, guanine, and cytosine. Adenine and guanine are purine-type bases; thymine and cytosine are pyrimidine-type bases (Fig. 135–6). These nucleotides are connected linearly to form a chain. Each DNA molecule is made up of two chains of nucleotides, which wind around each other to form a double helix. The two strands are held together by chemical bonding between the bases. The bonding process is very specific—adenine binds only with thymine, and guanine binds only with cytosine. This is known as complementary base pairing. RNA is important in the DNA-directed synthesis of proteins or enzymes. RNA differs from DNA in that it is composed of a single strand of nucleotides, the sugar is ribose, and the base uracil is substituted for thymine. There are three known types of RNA: messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA).

DNA SYNTHESIS

During the DNA synthesis phase, which takes place in the cell nucleus, the DNA unwinds and exposes its nucleotides. When DNA unwinds for replication or protein synthesis, only the portion of the molecule containing the needed nucleotides needs to be exposed. Rather than unwinding the entire strand, topoisomerase I and II enzymes cleave the DNA strands to facilitate unwinding of the section that is needed. The enzyme DNA polymerase

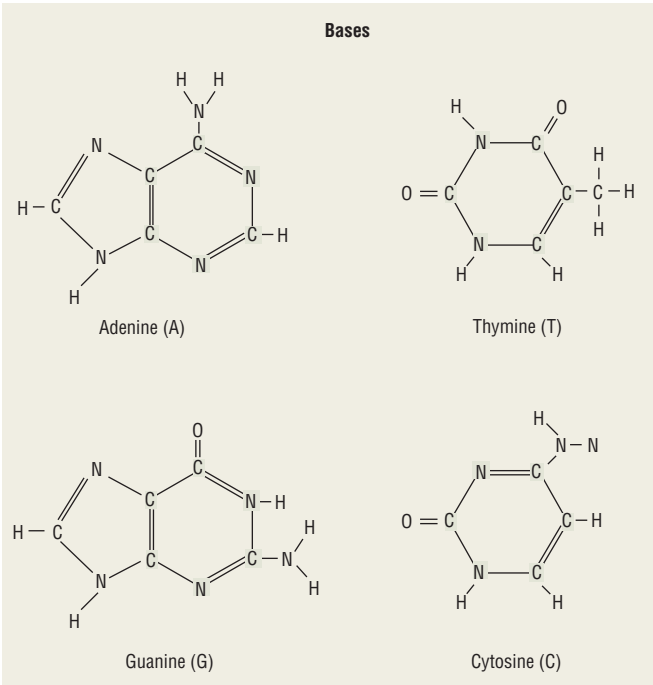

FIGURE 135-6. Structures of DNA constituents.

matches free complementary nucleotides from the environment to the exposed nucleotides of the DNA. The newly created strands rewind, resulting in two complete double helices. The topoisomerase enzymes are also responsible for resealing the cleaved DNA strands.

PROTEIN SYNTHESIS

The synthesis of proteins is a more complex process. Proteins consist of chains of amino acids in very specific sequences. As in DNA synthesis, the double helix must unwind. However, in protein synthesis, only the portion of the DNA molecule that codes for the desired protein is exposed. The enzyme RNA polymerase matches free complementary RNA nucleotides to the exposed DNA nucleotides, and the resultant chain of nucleotides is called mRNA. This process is called transcription. The mRNA travels to ribosomes in the cytoplasm, where protein synthesis occurs. Each three nucleotides of the mRNA chain compose a codon, whose sequence is specific for a particular amino acid. The codon is recognized by tRNA, which then carries the amino acid to the ribosome, where it is added to the growing peptide chain. This process is known as translation. The completed protein is then ready for its intended use as an enzyme or as a structural component.

CLINICAL PHARMACOLOGY OF CHEMOTHERAPY AND ENDOCRINE AGENTS

Anticancer agents are commonly categorized by their mechanism of action or by their origin. Alkylating agents exert their effects on DNA and protein synthesis by binding to DNA and preventing the unwinding of the DNA molecule. Antimetabolites resemble naturally occurring nuclear structural components ("metabolites"), such as the nucleotide bases, or inhibit enzymes involved in the synthesis of DNA and proteins. Antitumor antibiotics derive their name from their source; they are fermentation products of *Streptomyces* species. Figure 135–7 shows the sites of action of common categories of anticancer agents. The following section addresses these and other classes of agents used in the treatment of cancer. The clinical uses, mechanisms, side effects, and practical patient management for commonly used agents in each class are detailed. Table 135–8 summarizes dose modifications of individual agents.

ANTIMETABOLITES

Antimetabolites are similar to the nucleotides that make up DNA and RNA. The body mistakes these anticancer agents for the naturally occurring nucleotide bases and metabolizes these drugs as the natural nucleotides. These anticancer agents ultimately disrupt replication and cell division by interfering with the production of nucleic acids, DNA, and RNA. Unfortunately, these compounds are not selective for malignant cells, and rapidly dividing healthy cells may be poisoned by these agents. The most common adverse events associated with the antimetabolites are secondary to a direct cytotoxic effect of these agents on rapidly dividing healthy cells, such as the bone marrow cells. The three major classes of antimetabolites include pyrimidines, purines, and folate antagonists.

Fluorinated Pyrimidines

5-Fluorouracil Originally synthesized in the late 1950s, fluorouracil (5-FU) is a fluorinated analog of uracil. It is a prodrug and undergoes sequential phosphorylation to a mono-, di- and triphsophate similar to natural nucleotide bases to become an active anticancer agent. In the presence of folates, fluorodeoxyuridine monophosphate binds tightly to and interferes with the function of thymidylate synthase. This enzyme is required for synthesis of thymidine, one of the four essential building blocks of DNA. The triphosphate metabolite is incorporated into RNA as a false base, and interferes with its function. Interference with both thymidine formation and RNA function is important in producing the cytotoxic effects of 5-FU. Although 5-FU nucleotides can also be incorporated directly into DNA and affect its stability, the contribution to cell damage remains unclear. The method of administration influences the mechanism of action, with thymidylate synthesis inhibition playing a greater role in continuous-infusion regimens, and incorporation into RNA being more important for intermittent bolus schedules.[21]

Several pharmacologic strategies have been attempted to increase the cytotoxicity of 5-FU against tumor cells and to decrease its toxicity to normal cells. The most strategy combines 5-FU with the reduced folate leucovorin. Folates increase the stability of the fluorodeoxyuridine monophosphate–thymidylate synthase complex, thereby increasing the cytotoxicity and clinical usefulness of the 5-FU.[21]

Oral Fluoropyrimidines Capecitabine is an orally active pyrimidine analog of uracil and is a prodrug of 5-FU. Because capecitabine is enzymatically converted to 5-FU, it shares the same mechanisms of action. It generates higher levels of 5-FU selectively within some tumors compared with healthy tissues. Because chronic twice-daily oral dosing of capecitabine produces sustained 5-FU levels similar to continuous intravenous infusions of 5-FU, the toxicity pattern is similar to that of 5-FU infusions.[21,22]

The most common toxicities of fluoropyrmidines include neutropenia, thrombocytopenia, and anemia when administered as an IV bolus administration and hand–foot syndrome and diarrhea when administered as a continuous IV infusion.[21,22]

Cytidine Analogs

Cytarabine Cytarabine (ara-C) is an arabinose analog of cytosine. Ara-C is phosphorylated to its active triphosphate form (ara-CTP) within tumor cells and ara-CTP inhibits DNA polymerase, an enzyme responsible for strand elongation. It is also incorporated directly into DNA, where it inhibits the replication of DNA and acts as a chain terminator to prevent DNA elongation. Deaminase enzymes, particularly cytidine deaminase, degrades ara-C to an inactive form ara-U.[21,23]

Cytidine deaminase levels are very low in the CNS. Cytotoxic concentrations are maintained in the CNS for several hours after intrathecal administration of traditional cytarabine formulations, and for more than 2 weeks following administration of a depot formulation.

The toxicity of cytarabine is dose dependent. The most characteristic toxicity of high-dose ara-C (>1 g/m^2 per dose) is a cerebellar syndrome of dysarthria, nystagmus, and ataxia. Risk of CNS toxicity is strongly correlated with advanced age and renal dysfunction. Renal insufficiency permits accumulation of high levels of ara-CTP, which is believed to be neurotoxic. Hepatic dysfunction, high cumulative doses, and bolus dosing may also increase the risks of neurotoxicity.[21,23]

Gemcitabine Gemcitabine is a fluorine-substituted deoxycytidine analog related structurally to cytarabine. Its activation and mechanism of action are similar to those of cytarabine. Gemcitabine is incorporated into DNA, where it inhibits DNA polymerase activity. It also inhibits ribonucleotide reductase, which is the enzyme required to convert ribonucleotides into the deoxyribonucleotide forms needed for both DNA synthesis and

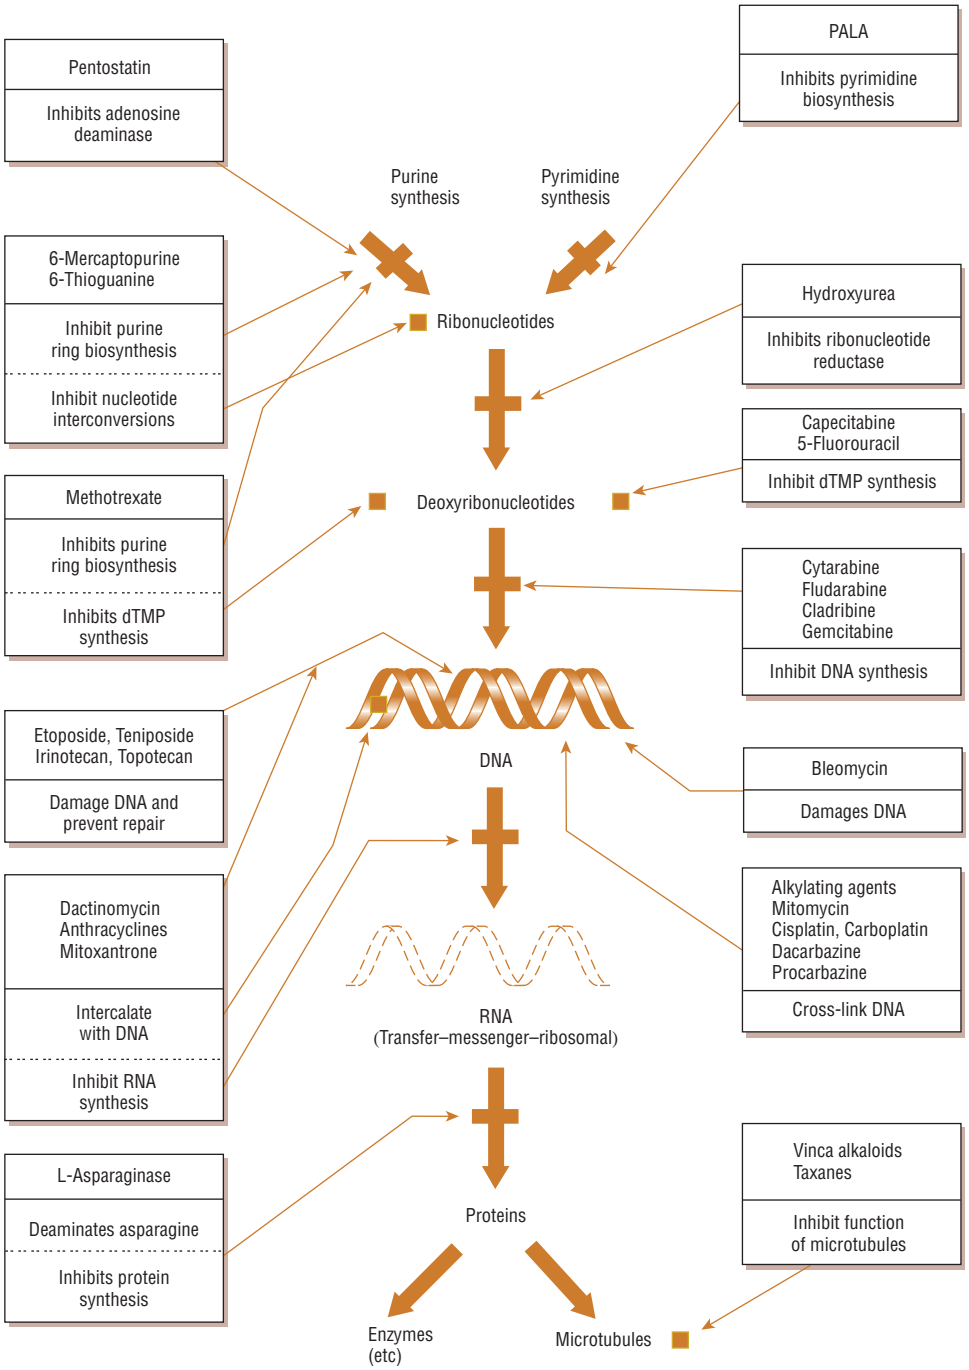

FIGURE 135-7. Mechanisms of action of commonly used anticancer agents. (dTMP, deoxythymidylic acid; PALA, *N*-phosphonacetyl-L-aspartate.) *(From Chabner BA, Amrein PC, Druker BJ, et al. Antineoplastic agents. In: Brunton LL, Lazo JS, Parker KL, eds. Goodman & Gilman's The Pharmacologic Basis of Therapeutics, 11th ed. New York: McGraw-Hill, 2006:1319.)*

repair. Compared with cytarabine, gemcitabine achieves intracellular concentrations about 20 times higher than does ara-C, secondary to increased penetration of cell membranes, and greater affinity for the activating enzyme deoxycytidine kinase. Gemcitabine that is incorporated into DNA has a prolonged intracellular half-life. Its stereoconfiguration causes another normal base pair to be added next to the fraudulent gemcitabine base pair in the DNA strand. This "masked chain termination" protects the gemcitabine from excision and elimination.[21,23]

Azacytidine and Decitabine Azacytidine was approved in 2004 and decitabine in 2006 for the treatment of patients with myelodysplastic syndrome, a disorder of hematopoietic cell maturation that can progress to acute myeloid leukemia. Both of these agents are nucleoside analogs, and they are believed to exert their pharmacodynamic effects by direct incorporation into DNA and inhibition of DNA methyltransferase, which cause hypomethylation of DNA.[24] Cellular differentiation, and apoptosis are believed to result from this effect. The cytotoxicity of these agents may also be attributed to the formation of covalent adducts between DNA methyltransferase and active drug being incorporated into DNA, particularly in cells actively dividing. Hypomethylation of DNA also appears to normalize the function of genes that control cell differentiation and proliferation, promoting normal cell maturation.[24]

These agents have demonstrated efficacy in slowing the progression of myelodysplastic syndrome to acute myelogenous leukemia, reducing transfusion requirements and allowing for the improvement of normal hematopoiesis over time. The primary toxicity is myelosuppression, particularly during early phases of treatment

TABLE 135-8 Empiric Dose Modifications in patients with Renal and Hepatic Disease[a]

Agent	Organ Dysfunction	Dose Modification
Bleomycin	CrCl = 30–60 mL/min (0.50–1.0 mL/s)	25%–50% decrease
	CrCl = 10–30 mL/min (0.17–0.50 mL/s)	25%–50% decrease
	CrCl <10 mL/min (<0.17 mL/s)	50% decrease
Capecitabine	CrCl = 30–50 mL/min (0.50–0.84 mL/s)	25% decrease
	CrCl <30 ml/min (<0.50 mL/s)	Do not use
Carboplatin	Renal insufficiency	Total Dose = AUC × (CrCl [in mL/min] + 25)
Cisplatin	Use with caution in patients with CrCl <50 mL/min (<0.84 mL/s)	
Cyclophosphamide	Renal failure	Decrease dose 25%
Etoposide	Decrease in proportion to CrCl:	Decrease dose 25%
	15–50 mL/min (0.25–0.84 mL/s)	
Fludarabine, hydroxyurea	Use in caution in patients with CrCl <60 mL/min (<1.0 mL/s)	Decrease dose in proportion to CrCl
Ifosfamide	CrCl = 10–50 mL/min (0.17–0.84 mL/s)	Decrease dose 25%
	CrCl = <10 mL/min (<0.17 mL/s)	Decrease dose 50%
Methotrexate	Decrease in proportion to CrCl	80 mL/min (1.34 mL/s)–full dose
	Monitor levels closely in all patients receiving high-dose therapy (e.g., ≥150 mg/m^2)	80 mL/min (1.34 mL/s)–75%
		60 mL/min (1.00 mL/s)–63%
		50 mL/min (0.84 mL/s)–56%
		< 50 mL/min (< 0.84 mL/s)–use alternative chemotherapy
Pentostatin	Dose in proportion to CrCl	
Streptozocin	Renal Failure	Decrease dose 50%–75%
Topotecan	CrCl 20–39 mL/min (0.33–0.65 mL/s)	Decrease dose 50%
	CrCl <20 ml/min (<0.33 mL/s)	Do not use
Anthracyclines	Bilirubin 1.2–3.0 mg/dL (20.5– 51.3 µmol/L)	Decrease dose 50%
	Bilirubin 3.1–5.0 mg/dL (53.0– 85.5 µmol/L)	Decrease dose 75%
	Bilirubin >5.0 mg/dL (>85.5 µmol/L)	Omit
Docetaxel	Bilirubin > ULN	Do not give
	AST or ALT >1.5 ULN and	Do not give
	Alk Phos >2.5 ULN	
Etoposide	Bilirubin 1.5–3.0 mg/dL (25.7– 51.3 µmol/L)	Decrease dose 50%
	Bilirubin 3.1–5.0 mg/dL (53.0– 85.5 µmol/L)	Omit
Imatinib	Bilirubin >3 × ULN	Withhold until <1.5 ULN
Ixabepilone	As a monotherapy agent if AST or ALT >10 × ULN or bilirubin >3 × ULN	Contraindicated
	In combination with capecitabine AST or ALT >2.5 × ULN or bilirubin >1 × ULN	
Lapatinib	Child–Pugh class C hepatic dysfunction	Dose reduction to 750 mg/day
Paclitaxel	Use with caution in hepatic failure	
Thiotepa	Use with caution in hepatic failure	
Vinblastine, vincristine	Bilirubin 1.5–3.0 mg/dL (25.7–51.3 µmol/L)	Decrease dose 50%
	Bilirubin 3.1–5.0 mg/dL (53.0–85.5 µmol/L)	Omit
Vinorelbine	Bilirubin 2.1–3.0 mg/dL (35.9–51.3 µmol/L)	Decrease dose 50%
	Bilirubin >3 mg/dL (51.3 µmol/L)	Decrease dose 75%

CrCl, creatinine clearance; ULN, upper limit of normal laboratory values. Renal failure: creatinine clearance <25 mL/min (<0.42 mL/s).
[a]Only approximate guidelines can be given. See text for explanations and limitations. Consult current references prior to dispensing as not all dose adjustments are provided in the table.

as the malignant clone driving myelodysplastic syndrome is cleared from the bone marrow and normal hematopoiesis is slowly restored. As a result, infectious complications occur frequently.

Purines and Purine Antimetabolites

Mercaptopurine and Thioguanine 6-Mercaptopurine (MP) was the first purine analog to be used in cancer chemotherapy. Thioguanine is the two-amino analog of 6-MP. Both agents are rapidly converted to ribonucleotides that inhibit purine biosynthesis. They also undergo purine interconversion reactions needed to supply purine precursors for synthesis of nucleic acids. Clinical cross-resistance is generally observed.[21] Both anticancer agents are metabolized by thiopurine methyltransferase (TPMT) and hypoxanthine phosphoribosyl transferase to produce multiple metabolites responsible for the efficacy, hepatic toxicity and myelosuppression associated with these agents. Genetic polymorphsims of TPMT are associated with reduced enzyme activity and decreased tolerance of standard doses of 6-MP.

MP depends on xanthine oxidase for an initial oxidation step. Its metabolism is markedly decreased by concomitant administration of the xanthine oxidase inhibitor allopurinol, and serious toxicity may result. Oral MP doses must be reduced when allopurinol is administered together with 6-MP.[21]

Fludarabine Monophosphate Fludarabine monophosphate is an analog of the purine adenine. Like cytarabine, fludarabine interferes with DNA polymerase, causing chain termination. Fludarabine also incorporates into RNA, resulting in inhibited transcription. The usual dose-limiting toxicity is myelosuppression. Fludarabine is also immunosuppressive, with associated opportunistic infections resulting from fludarabine's effect on T cells and a subsequent decrease in CD4 counts; prophylactic antibiotics and antiviral medications are recommended and should continue until CD4 counts normalize.[21,25]

Cladribine and Pentostatin Cladribine and pentostatin are purine nucleoside analogs with slightly different mechanisms of action. Cladribine is resistant to inactivation by adenosine deaminase and triphosphorylated to an active form that is incorporated

into DNA, resulting in inhibition of DNA synthesis and early chain termination. Cladribine's antitumor activity is unusual for an antimetabolite in that it affects both actively dividing and resting cancer cells. Pentostatin is a potent inhibitor of adenosine deaminase. Adenosine deaminase is an enzyme critical in purine base metabolism and is found in high concentrations in lymphatic tissue. Like fludarabine, these agents possess immunosuppressive effects that place patients at risk for serious opportunistic infections.[21,23]

Antifolates

Folate vitamins are essential cofactors in DNA synthesis. They carry one-carbon groups in transfer reactions that are required for purine and thymidylic acid synthesis, and, in turn, for formation of DNA and for cell division. Natural folates circulating in the blood have a single glutamic acid group, but within cells they are converted to polyglutamates, which are more efficient cofactors and preferentially retained inside the cells.[26]

Dietary folates must be chemically reduced to their tetrahydro forms, with four hydrogens on the pteridine ring, to be active. The enzyme responsible for this reduction is dihydrofolate reductase (DHFR), a key enzyme whose actions are inhibited by methotrexate and other antifolates. The result of this inhibition is depletion of intracellular pools of reduced folates (tetrahydrofolates) essential for thymidylate and purine synthesis. Lack of either thymidine or purines prevents synthesis of DNA. The DHFR-mediated effects of antifolate drugs on normal and probably also on cancerous cells may be neutralized by supplying reduced folates exogenously. The reduced folate used clinically for "rescue" is leucovorin (folinic acid), which bypasses the metabolic block induced by DHFR inhibitors.[26]

Methotrexate The folic acid analog methotrexate (MTX) is the best understood of all drugs in the broad category of antimetabolites. It has been in clinical use for more than 50 years. Like physiologic folates, MTX is transported intracellularly by an active transport system. In high doses, passive diffusion may overcome tumor cell resistance caused by saturated active transport systems. Resistance to the antifolates can also be caused by amplification of DHFR. Other potential causes of resistance are slow rates of thymidylate synthesis, decreased affinity of DHFR for MTX, and lack of polyglutamation within tumor cells. Polyglutamated forms of folates are better retained within cells. Malignant cells may achieve greater MTX polyglutamate levels than normal cells, which may, in part, explain the selective effects of MTX on malignant versus normal cells.[26]

Accurate and readily available assays for serum MTX levels have made therapeutic drug monitoring of MTX a valuable clinical tool. The threshold for cytotoxic effects of MTX is approximately 0.02 mg/L (50 nmol/L). Toxicity and efficacy relates not only to peak concentrations, but more importantly, to time that concentrations remain above this threshold level. For MTX doses requiring leucovorin rescue (generally doses greater than 1,000 mg/m^2), leucovorin must be administered until levels fall below 0.02 mg/L (50 nmol/L). Therapeutic drug monitoring is also an effective means of increasing the likelihood of therapeutic success, by individualizing doses based on target levels.[26]

Pemetrexed Pemetrexed is a multitargeted antifolate that inhibits at least three biosynthetic pathways in thymidine and purine synthesis. In addition to inhibition of DHFR, it also inhibits thymidine synthase and glycinamide ribonucleotide formyltransferase, decreasing the risk of the development of drug resistance. Severe hematologic toxicity and deaths associated with neutropenic sepsis have been reported in clinical trials with pemetrexed. Elevated baseline cystathionine or homocysteine concentrations correlated with this unexpected toxicity. Routine supplementation of folic acid and vitamin B_{12} lowers levels of these substances and lowers the risk of mortality related to neutropenic sepsis. The approved labeling of pemetrexed requires administration of folic acid and vitamin B_{12} throughout the duration of treatment.[18,26]

Antifolates are associated with neutropenia and thrombocytopenia, mucositis, and nausea and vomiting. Renal tubular necrosis is seen with high-dose MTX therapy and vigorous hydration with or without alkalinization of the urine necessary to decrease risk of renal failure.

MICROTUBULE-TARGETING DRUGS

Vinca Alkaloids

Vincristine, vinblastine, and vinorelbine are natural alkaloids derived from the periwinkle (vinca) plant. They act as mitotic inhibitors, or "spindle poisons." Although the alkaloids are very similar structurally, they have different activities and patterns of toxicity. Vinorelbine and vinblastine are associated with dose-limiting myelosuppression, whereas vincristine causes mild myelosuppressive effects but is more neurotoxic.

Vinca alkaloids bind to tubulin, the structural protein that polymerizes to form microtubules. These are the hollow tubes that make up the mitotic spindle and that are also important in nerve conduction and neurotransmission. Vinca alkaloids disrupt the normal balance between polymerization and depolymerization of microtubules, inhibiting assembly of microtubules and disrupting microtubule dynamics. This interferes with formation of the mitotic spindle and causes cells to accumulate in mitosis. They also disturb a variety of microtubule-related processes in cells, and induce apoptosis. Resistance to the vinca alkaloids develops primarily from P-glycoprotein (Pgp)–mediated multidrug resistance, which decreases drug accumulation and retention within tumor cells.[27]

Taxanes

Paclitaxel and docetaxel are taxane plant alkaloids with antimitotic activity. Paclitaxel was isolated from the bark of the Pacific yew tree, *Taxus brevifolia*, but is now produced semisynthetically from the needles of the European yew, *Taxus baccata*. Docetaxel is a semisynthetic taxoid extracted from 10-deacetyl baccatin III, a noncytotoxic precursor found in the renewable needle biomass of yew plants.[27]

Paclitaxel and docetaxel both act by binding to tubulin, but unlike the vincas, they do not interfere with tubulin assembly. Instead, the taxanes promote microtubule assembly and therefore interfere with microtubule disassembly. They induce tubulin polymerization, resulting in formation of inappropriately stable, nonfunctional microtubules. The stability of the microtubules damages cells, because the dynamics of microtubule-dependent structures required for mitosis and other cellular functions are disrupted. Taxanes also have some nonmitotic actions that can promote cancer cell death, such as inhibition of angiogenesis. Resistance to the antitumor effects of the taxanes is attributable to alterations in tubulin or tubulin binding sites, or to Pgp multidrug resistance. Although paclitaxel and docetaxel have very similar mechanisms of action, cross-resistance between the two agents is incomplete.[27] Myelosuppression is common with both agents but other adverse effects can differ. Increased fluid retention is seen with docetaxel, whereas increased neurotoxicity and hypersensitivity reactions are seen with paclitaxel.[18,27] Both agents require premedications with corticosteroids; paclitaxel also requires antihistamines to decrease the likelihood of allergic reactions.

To circumvent the hypersensitivity reactions with paclitaxel, and possibly increase its efficacy, paclitaxel was formulated to be bound to albumin (nab-paclitaxel). This new dosage form is devoid of the Cremophor excipient that is believed to mediate the hypersensitivity reactions and exacerbate myelosuppression with the conventional formulation. This formulation appears to be selectively activated by tumor cells to the active paclitaxel compound.[28] In comparative clinical trials, this novel compound has shown comparable activity to the conventional formulation of paclitaxel with a lower incidence of hypersensitivity reactions. Peripheral neuropathies remain a common adverse effect with this formulation.

Epothilones

Similar to the taxanes, the epothilones work in the M phase of the cell cycle. Epothilone binding to microtubules is distinct from taxanes with activity demonstrated in paclitaxel-resistant cell lines.[29] Epothilones appear to be poor substrates for Pgp and their cytotoxicity is not affected by its overexpression. Natural epothilones are macrolide derivatives that have stability and pharmacokinetic problems. Synthetic agents have been developed with the first agent, ixabepilone, approved for the treatment of metastatic breast cancer. Toxicities are similar to taxanes; premedication with antihistamines are required, although no corticosteroid is administered unless the patient experiences an allergic reaction to a previous dose.

Estramustine

Estramustine is an unusual drug because it structurally combines the alkylating agent *nor*-nitrogen mustard with the hormone estradiol.[18] It was designed with the intent that the estradiol portion of the molecule would facilitate uptake of the alkylating agent into hormone-sensitive prostate cancer cells. Despite the inclusion of an alkylator, estramustine does not function in vivo as an alkylating agent. Estrogens are released after its administration and are responsible for most of the toxicity of estramustine, but are not believed to contribute to its cytotoxic effect. In the mid 1980s, estramustine was redefined as an antimicrotubule agent. It binds covalently to microtubule-associated proteins that are part of the structural support for microtubules. The binding causes the separation of microtubule-associated proteins from the microtubules, inhibiting microtubule assembly and eventually causing their disassembly.[18]

TOPOISOMERASE INHIBITORS

Topoisomerases are essential enzymes involved in maintaining DNA topologic structure during replication and transcription. DNA topoisomerase enzymes relieve torsional strain during DNA unwinding by producing strand breaks. They cleave DNA strands and form intermediates with the strands, producing a gap through which DNA strands can pass, then reseal the strand breaks. Topoisomerase I produces single-strand breaks; topoisomerase II produces double-strand breaks.[30] Several important anticancer agents target topoisomerase enzymes: camptothecins, anthracyclines, and the epipodophyllotoxins.

Camptothecin Derivatives

The camptothecin analogs irinotecan and topotecan were synthesized to reduce toxicity and improve therapeutic effects of camptothecin, a plant alkaloid derived from *Camptotheca acuminata*. Both topotecan and irinotecan, through its active metabolite SN-38, inhibit topoisomerase I enzyme activity. Topoisomerase I enzymes stabilize DNA single-strand breaks and inhibit strand resealing.[30,31] Irinotecan undergoes metabolism to SN-38 by the polymorphic enzyme uridine diphosphate glucosyltransferase and variant tandem repeats in the promoter of this gene are associated with a higher risk of diarrhea and neutropenia.

Etoposide And Teniposide

Etoposide and teniposide are semisynthetic podophyllotoxin derivatives that bind to tubulin and interfere with microtubule formation. Etoposide and teniposide also damage tumor cells by causing strand breakage through inhibition of topoisomerase II.[30] Resistance may be caused by differences in topoisomerase II levels, increased cell ability to repair strand breaks, or increased levels of Pgp. Etoposide and teniposide are usually clinically cross-resistant. They are cell-cycle phase-specific and arrest cells in the S or early G_2 phase. As a result, activity is much greater when they are administered in divided doses over several days, rather than in large single doses.

Anthracene Derivatives

The most widely used and best understood anthracene derivative is doxorubicin, also commonly known by its earliest trade name, Adriamycin or "Adria." Other members of the anthracene group include daunorubicin (daunomycin), idarubicin, epirubicin, and mitoxantrone. All of these agents, except mitoxantrone, are anthracyclines and share a common, four-membered anthracene ring complex with an attached aglycone or sugar portion. The ring complex is a chromophore and accounts for the intense colors of these compounds. Doxorubicin differs from its parent compound daunorubicin by the addition of a hydroxyl group on the attached sugar, and it is sometimes referred to as hydroxydaunorubicin. A hydroxyl group on epirubicin is in the *epi* conformation compared with doxorubicin (epidoxorubicin), and idarubicin is demethoxydaunorubicin. Mitoxantrone is an anthracenedione rather than an anthracycline, and has no sugar group attached to the three-membered, anthracene ring complex.[30,32]

Doxorubicin, Daunorubicin, Idarubicin, and Epirubicin

Anthracyclines are classified as antitumor antibiotics, but it is more accurate to refer to them as intercalating topoisomerase inhibitors. Intercalating agents are compounds that insert or stack between base pairs of DNA. Although it is well established that the planar groups of the anthracene ring complex do intercalate with DNA, causing structural changes that interfere with DNA and RNA synthesis, this is not their primary mechanism of cytotoxicity. The anthracyclines are primarily topoisomerase II inhibitors, producing double-strand DNA breaks.[18,30,32]

The anthracyclines also undergo electron reductions to reactive compounds that can damage DNA and cell membranes. Free radicals formed from reduction of the anthracyclines first donate electrons to oxygen to make superoxide, which can react with itself to make hydrogen peroxide. Cleavage of hydrogen peroxide produces the highly reactive and destructive hydroxyl radical. This last step requires iron, and the anthracyclines are potent iron binders. Iron–anthracycline complexes can bind to DNA and react rapidly with hydrogen peroxide to produce the hydroxyl radicals that actually cleave DNA. Human cells have natural defenses against oxygen radical damage, in the form of enzymes that can convert the radicals to less reactive compounds, or that can repair DNA damage. Differences in distribution of these defensive enzymes may account for the cardiotoxicity of the anthracyclines. For example, cardiac muscle has low levels of defensive enzymes and high levels of enzymes that activate anthracyclines. Oxygen

free-radical formation is firmly established as a cause of cardiac damage and extravasation injury, but is not a major mechanism of tumor-cell killing. Resistance to the anthracyclines is usually secondary to Pgp–dependent multidrug resistance, causing the anthracyclines to be actively pumped out of tumor cells. Altered topoisomerase II activity may contribute to the development of resistance.[18,32]

Mitoxantrone The anthracenedione mitoxantrone was synthesized in an attempt to develop agents with comparable antitumor activity to doxorubicin, but with an improved safety profile. Like the anthracyclines, mitoxantrone is an intercalating topoisomerase II inhibitor, but its potential for free-radical formation is much less than that of the anthracyclines. This decreased tendency for free-radical formation may explain the reduced risks of cardiac toxicity and ulceration after extravasation.[18,32]

ALKYLATING AGENTS

The alkylating agents are among the oldest and most useful classes of anticancer agents. Their clinical use evolved from the observation of bone marrow suppression and lymph node shrinkage in soldiers exposed to sulfur mustard gas warfare during World War I.[18] In an effort to develop similar agents that might be useful in treating cancerous overgrowths of lymphoid tissues, less-reactive derivatives were synthesized. Their effectiveness as anticancer agents was confirmed by clinical trials in the middle 1940s.

All of the alkylating agents work through the covalent bonding of highly reactive alkyl groups or substituted alkyl groups with nucleophilic groups of proteins and nucleic acids. Some alkylating agents react directly with biologic molecules; others form an intermediate compound that reacts with the targets. The most common binding site for alkylating agents is the seven-nitrogen group of guanine. These covalent interactions result in cross-linking between two DNA strands or between two bases in the same strand of DNA. Reactions between DNA and RNA and between drug and proteins may also occur, but the main insult that results in cell death is inhibition of DNA replication, because the interlinked strands do not separate as required. Because the alkylating agents can damage DNA during any phase of the cell cycle, they are not cell-cycle phase-specific. However, their greatest effect is seen in rapidly dividing cells.

As a class, alkylators are cytotoxic, mutagenic, teratogenic, carcinogenic, and myelosuppressive. Resistance to these agents can occur from increased DNA repair capabilities, decreased entry into or accelerated exit from cells, increased inactivation of the agents inside cells, or lack of cellular mechanisms to result in cell death following DNA damage. They react with water and are inactivated by hydrolysis, making spontaneous degradation an important component of their elimination.[33]

Nitrogen Mustards

Cyclophosphamide and ifosfamide are nitrogen mustard derivatives, and are widely used alkylating agents in the treatment of solid tumors and hematologic malignancies. They are closely related in structure, clinical use, and toxicity. Neither agent is active in its parent form and must be activated by mixed hepatic oxidase enzymes including the cytochrome P450 (CYP) 2B6 and CYP3A4 enzymes. The active metabolite of cyclophosphamide is phosphoramide mustard. Another metabolite, 4-hydroxycyclophosphamide is cytotoxic, but is not an alkylating agent. Ifosfamide is hepatically activated to ifosfamide mustard. Acrolein, a metabolite of both cyclophosphamide and ifosfamide, has little antitumor activity, but is responsible for the hemorrhagic cystitis associated with ifosfamide and sometimes high-dose cyclophosphamide.[33] Encephalopathy following ifosfamide can occur within 48 to 72 hours following the infusion and is reversible. The increased production of dechloroethylated metabolites following administration of ifosfamide compared with cyclophosphamide may explain the increased risk of central nervous system toxicity associated with ifosfamide.[34]

Bendamustine is an alkylating agent (nitrogen mustard derivative) with a benzimidazole ring (purine analog) that demonstrates only partial cross-resistance (in vitro) with other alkylating agents.[35] It leads to cell death via single and double strand DNA cross-linking. Bendamustine is active against quiescent and dividing cells. The primary cytotoxic activity is due to bendamustine rather than its metabolites. It is used primarily to treat lymphoid malignancies such as chronic lymphocytic leukemia and non-Hodgkin lymphoma.

Nitrosoureas

The nitrosoureas are alkylating agents characterized by lipophilicity and ability to cross the blood–brain barrier. Carmustine or bischloroethylnitrosourea (BCNU) and lomustine (CCNU) are commercially available. BCNU is available as an intravenous preparation and as a drug-impregnated biodegradable wafer (Gliadel) for direct application to residual tumor tissue following surgical resection of brain tumors. The nitrosoureas decompose to reactive alkylating metabolites and to isocyanate compounds that have several effects on reproducing cells.[33]

Nonclassic Alkylating Agents

Several other cytotoxic agents appear to act as alkylators, although their structures do not include the classic alkylating groups. They are capable of binding covalently to cellular components and include procarbazine, dacarbazine, temozolomide, the heavy metal compounds, and some antitumor antibiotics.[33]

Dacarbazine and Temozolomide Dacarbazine (DTIC) and temozolomide are nonclassic alkylating agents. Both compounds undergo demethylation to the same active intermediate (monomethyl triazeno-imidazole-carboxamide [MTIC]) that interrupts DNA replication by causing methylation of guanine. Unlike dacarbazine, temozolomide does not require the liver for activation, and is chemically degraded to MTIC at physiologic pH. Both agents inhibit DNA, RNA, and protein synthesis.[18,33]

Important pharmacokinetic differences exist between the two agents. Dacarbazine is poorly absorbed, and must be administered by intravenous infusion. Temozolomide is rapidly absorbed after oral administration, and is nearly 100% bioavailable when given on a completely empty stomach. Dacarbazine penetrates the CNS poorly, but temozolomide readily crosses the blood–brain barrier, achieving therapeutically active concentrations in cerebrospinal fluid and brain tumor tissues.[18,33]

HEAVY METAL COMPOUNDS

Cisplatin, Carboplatin, and Oxaliplatin

The platinum derivatives—cisplatin, carboplatin, and oxaliplatin—are anticancer agents with remarkable usefulness in cancer treatment. Recognition of cisplatin's cytotoxic activity was the result of a serendipitous observation that bacterial growth in culture was altered when an electric current was delivered to the media through platinum electrodes. The growth change was noted to be similar to that produced by alkylating agents and radiation. It was found that a platinum–chloride complex, now known as cisplatin, generated by the current was responsible for the changes. Carboplatin is a structural analog of cisplatin in which the chloride

groups of the parent compound are replaced by a carboxycyclobutane moiety. It shares a similar spectrum of clinical activity with cisplatin, and cross-resistance is common. Oxaliplatin is an organoplatinum compound in which the platinum is complexed with an oxalate ligand as the leaving group and to diaminocyclohexane. Its spectrum of activity differs substantially from the other platinum compounds, and includes notable activity against colorectal cancers.[18,33]

The cytotoxicity of the platinum derivatives depends on platinum binding to DNA and the formation of intrastrand cross-links or adducts between neighboring guanines. These intrastrand links cause a major bending of the DNA. They may cause cellular damage by distorting the normal DNA conformation and preventing bases that are normally paired from lining up with each other. Interstrand cross-links also occur.[18,33]

The cytotoxic form of cisplatin is the aquated species, in which hydroxyl groups or water molecules replace the two chloride groups. This reaction occurs readily in low concentrations of chloride, such as the concentrations present within cells, and produces a positively charged compound that can react with DNA. The aquated species is responsible for both the efficacy and toxicity of cisplatin. Carboplatin also undergoes aquation, but at a slower rate. Oxaliplatin becomes active when the oxalate ligand is displaced in physiologic solutions.[18,33]

Resistance to the therapeutic effects of platinum compounds may occur through several mechanisms. The ability to repair platinum-induced DNA damage may be increased, or the agents may be inactivated by increased levels of intracellular glutathione, metallothioneins, or other thiol-containing proteins. Altered uptake into cells may also affect sensitivity to platinum compounds.[18,33]

Cisplatin is a highly toxic anticancer agent that can cause serious nephrotoxicity, ototoxicity, peripheral neuropathy, emesis, and anemia. The significant efficacy of cisplatin against many tumor types makes it a valuable agent despite these toxicities, most of which can be prevented or managed with aggressive supportive care measures.[18] In contrast, carboplatin administration is limited by hematologic toxicity. Patients with compromised renal function require dose reductions to limit myelosuppressive toxicity.[18,33] The most widely used dosage schema, the Calvert formula (Table 135–9), uses a target area-under-the-curve and renal function parameters to estimate the carboplatin dose. Carboplatin's potential to cause renal damage, peripheral neuropathy, ototoxicity, and nausea and vomiting is much less than that of comparable cisplatin doses.[33] Oxaliplatin is not nephrotoxic or ototoxic, is moderately emetogenic, but can cause peripheral neuropathies and unique cold-induced neuropathies.[36] All of the platinum derivatives have potential to cause hypersensitivity reactions, including anaphylaxis, after a threshold exposure is reached.

TABLE 135-9 Dosing Formulas for Chemotherapy Agents[a]

DuBois and DuBois
BSA (m^2) = Wt $(kg)^{0.425}$ × Ht $(cm)^{0.725}$ × 0.007184
Mosteller
BSA (m^2) = √(Ht (cm) × Wt (kg)/3600)
Calvert (for carboplatin)
Dose $(mg)^a$ = AUC^b × ($CrCl^c$ + 25)

AUC, area-under-the-curve; BSA, body surface area; CrCl, creatinine clearance in mL/min; Ht, height; Wt, weight.

[a]Note that the dose is in total milligrams to be administered, not mg/m^2.

[b]AUC needs to be stated in the dosing protocol.

[c]Cockcroft and Gault equation often clinically used.

ENDOCRINE THERAPIES

Perhaps the earliest successful approach to target the growth processes of cancerous cells was the use of endocrine therapies. Endocrine manipulation is an option for management of cancers from tissues whose growth is under gonadal hormonal control, especially breast, prostate, and endometrial cancers. These cancers may regress if the "feeding" hormone is eliminated or antagonized. Major organ system toxicity is uncommon from hormonal treatment, making it the least toxic of systemic anticancer therapies. Increasingly specific agents such as the selective estrogen receptor modulators and aromatase inhibitors have increased the utility of hormonal therapies in the treatment of cancer.[37–39] These agents are discussed in detail in Chapters 136 and 139.

Corticosteroid hormones are also useful anticancer agents because of their lymphotoxic effects. Their primary use is in management of hematologic malignancies, especially lymphoid malignancies such as lymphomas, lymphocytic leukemias, and multiple myeloma. In addition to their cytotoxic effects, corticosteroids have many other applications in supportive care of cancer patients. Corticosteroids have diverse toxicities in chronic or high-dose use, but are generally well tolerated in the short-term therapies usually used in cancer patient care.[40]

MISCELLANEOUS AGENTS

Bleomycin

Bleomycin is an antitumor antibiotic. It is a mixture of peptides from fungal *Streptomyces* species, and its strength is expressed in units of drug activity.[18] One unit is roughly equal to 1 mg of polypeptide protein. The predominant peptide is bleomycin A2, which makes up approximately 70% of the commercial drug product. Bleomycin's cytotoxicity is secondary to DNA strand breakage, or scission, which it produces via free-radical formation. Cytotoxicity depends on binding of the bleomycin–iron complex to DNA. The bleomycin–iron complex then reduces molecular oxygen to free oxygen radicals that cause primarily single-strand breaks in DNA. Bleomycin has greatest effect on cells in the G_2 phase of the cell cycle and in mitosis.[18]

Bleomycin is inactivated within cells by the enzyme aminohydrolase. This enzyme is widely distributed, but is present in only low concentrations in the skin and the lungs, explaining the predominant toxicities of bleomycin to those sites. Baseline pulmonary function tests and monitoring for pulmonary toxicity is necessary during bleomycin therapy. The presence of hydrolase enzymes in tumor cells is the primary mechanism of resistance to bleomycin. Cells can also become resistant by repairing the DNA breaks produced by bleomycin.[18]

Hydroxyurea

Hydroxyurea is a unique drug that inhibits ribonucleotide reductase. Cells accumulate in the S phase because DNA synthesis is inhibited, and only abnormally short DNA strands are produced.[21] This drug is often used to cause a rapid decline in a patient's white blood cells prior to initiating more potent chemotherapy agents.

L-Asparaginase

L-Asparaginase is unique among anticancer agents in its unusual mechanism of action, patterns of toxicity, and source. It is an enzyme produced by *Escherichia coli* and other bacteria. L-Asparagine is a nonessential amino acid that can be synthesized by most mammalian cells, except for those of certain lymphoid human

malignancies, which lack or have very low levels of the synthetase enzyme required for L-asparagine formation.[18] L-Asparagine is degraded by the enzyme L-asparaginase, which depletes existing supplies and inhibits protein synthesis. Increased L-asparagine synthetase activity within tumor cells causes resistance to L-asparaginase treatment.[18]

Arsenic Trioxide

Arsenic is an organic element and a well-known poison that is an effective treatment for acute promyelocytic leukemia.[41] As an anticancer agent, arsenic trioxide acts as a differentiating agent, inducing the growth progression of cancerous cells into mature, more normal cells. It also induces programmed cell death or apoptosis.

Mitomycin C

Mitomycin C is a natural product that is sometimes classified as an antitumor antibiotic.[33,42] It has similarities to nitrogen mustard compounds and may function as an alkylating agent, although its toxicity pattern differs from conventional alkylating agents.

Vorinostat

Vorinostat belongs to a new class of anticancer agents referred to as HDAC inhibitors. As described in the section on epigenetics, HDAC catalyzes the removal of acetyl groups from the lysine residues of proteins, including histones and transcription factors.[12,43] By inhibiting HDAC activity, vorinostat causes the accumulation of acetylated histones and induces cell cycle arrest and apoptosis of cancer cells. Pulmonary embolism and deep vein thrombosis have been reported along with dose-related thrombocytopenia and anemia.

CLINICAL PHARMACOLOGY OF BIOLOGIC AND TARGETED AGENTS

Biologic agents include cytokines, monoclonal antibodies, growth factors, and vaccines. The newer biologic therapies (e.g., monoclonal antibodies) are frequently termed "targeted therapies" because they target specific tumor antigens. These newer therapies are designed to target pathways critical for the survival and growth of cancer cells. Several anticancer agents that target malignant cells or the biochemical processes that control cancerous cell growth are available to treat both solid and hematologic malignancies. These agents are designed to improve outcomes while minimizing adverse effects. Small molecules (-nibs) typically interfere with downstream intracellular signaling by binding to the target proteins within the cell. In comparison, the monoclonal antibodies (-mabs) bind to the extracellular receptor or to its natural ligand and prevent the activation of the downstream intracellular signaling. Well-described intracellular signaling pathways include PI3K and MAPK pathways and when activated, promote cell proliferation and survival. The downstream effectors of these pathways also initiate cell cycle progression by promoting the expression of cyclins and repressing the expression of CDK inhibitors. The small molecules and monoclonal antibodies ultimately suppress cell cycle progression, cell proliferation and survival by stopping the relay of the intracellular signals.

MONOCLONAL ANTIBODIES

6 Monoclonal antibodies have become established agents in the treatment of cancer. Monoclonal antibodies (MoABs) consist of immunoglobulin sequences that are known to recognize a specific antigen or protein on the surface of cells. There are five classes of immunoglobulins (IgA, IgD, IgE, IgG, and IgM), with IgG the most commonly used therapeutically. The fundamental structure of all antibodies is identical and consists of two heavy and two light chains joined to form a molecule that resembles the letter Y. The variable region (Fab fragment) of antibodies differs greatly and is composed of three complementary determining regions. The Fab portion is composed of heavy (V_H) and light chains (V_L) that are responsible for binding to antigens. The constant region (Fc fragment) determines the effector function of the antibody.[44]

Two main classes of MoABs are used in the treatment of cancer, the most common of which are unconjugated or naked MoABs. The other class is immunoconjugates, which are MoABs conjugated to a toxin (immunotoxin), chemotherapy agent, or radioactive particle (radioimmunoconjugate). MoABs may also be divided into agents that target cell surface antigens and induce cell death and those that target growth factor receptors or ligands.[44] Standardized nomenclature exists for naming MoABs and can provide information to the clinician.[45] The suffix -mab is used for all MoABs and fragments and is always preceded by the identification of the animal source of the product. The letters *o*, *u*, *xi*, and *zu* before the -mab suffix indicate a murine, human, chimeric, and humanized source, respectively. The general disease state the MoAB is treating precedes the source and is identified using a code. Currently, most approved MoABs used in cancer have the code syllabus -tu(m) that designates it for use against miscellaneous tumors. If the product is conjugated to another chemical, such as a toxin, or is radiolabeled, a separate word is added for this designation. In addition, the name of the isotope, element symbol, and isotope number should precede the name of the MoAB. For example, iodine I-131-tositumomab is a murine MoAB designated for use in cancer that is conjugated to the radioisotope iodine 131.

6 The first MoABs used in humans were murine, but most of the MoABs used today are chimeric, humanized, or fully human. These agents differ in the amount of foreign component. Hypersensitivity and infusion-related reactions, with or without the development of human antimouse antibodies (HAMAs), are generally greatest with murine antibodies and least with humanized antibodies.[44,46] Human antibodies would not be expected to cause HAMA reactions. However, clinicians should be careful when administering any MoAB as rare HAMA-like reactions have occurred to chimeric and humanized MoABs. The severity of these reactions can range from mild (e.g., fever, chills, nausea, and rash) to severe, life-threatening anaphylaxis with cardiopulmonary collapse. Many patients also experience chest or back pain during the infusion. Patients with circulating tumor cells in the bloodstream are at highest risk for more severe reactions. For these reasons, patients must be monitored closely during infusion. The reactions tend to be more severe with the initial infusion, and subside with subsequent treatment. Most agents require premedication with antihistamines and acetaminophen. Recommended infusion rates are usually lower for the initial dose, with incremental increases as tolerated by the patient. For patients experiencing signs or symptoms of infusion-related reactions, the infusion should be interrupted and prompt treatment with antihistamines, corticosteroids, and other supportive measures should be initiated. Pulmonary toxicity may occur as part of the infusion-related reaction or may occur as a distinct entity.[44,46,47]

HAMA reactions can also increase the clearance of the MoAB from the body by targeting the murine portion of the antibody as foreign. This will decrease the half-life of the MoAB and may decrease the ability of the MoAB to bind to its target antigen and potentially decrease its efficacy over time.

Additionally, the toxicities of the MoABs will be determined by the selectivity of the target antigen. Antibodies against antigens found on normal and tumor cells will have increased toxicity compared to tumor-specific antigens found only on tumor tissues. For example, gemtuzumab targets $CD33^+$ antigen, which is found on tumor and early myeloid cells. As a result, prolonged myelosuppression is an anticipated adverse effect of gemtuzumab.[44]

6 There are several mechanisms by which MoABs may induce death of cancer cells. Unconjugated MoABs that target antigens on the cell surface of cancer cells may directly mediate cell killing through complement activation (complement-dependent cytotoxicity [CDC]), antibody-dependent cellular toxicity (ADCC), or signaling the cascade of events that lead to tumor cell apoptosis.[44,46,48] CDC results when the Fc portion of the MoAB activates the complement system leading to tumor cell lysis. In ADCC, effector cells that contain Fc receptors bind to the Fc portion of the MoAB and either lyses or phagocytosizes the antibody-containing cell. Natural killer cells, monocytes, and macrophages are all capable of mediating ADCC. Finally, antibody binding may result in the transmission of signals that induce apoptosis, or programmed cell death in the targeted cell.

6 In addition to the mechanisms of cell death above, immunoconjugates deliver a chemotherapy agent or radioactive particle to the site of disease. Once bound to target antigens, the chemotherapy drug conjugated to the MoAB is internalized by the target cell and kills tumor cells through traditional mechanisms of action.[49] MoABs conjugated to radiation deliver radiation targeted to the site of tumor involvement, resulting in cell death. In addition to killing the target cell, radioimmunoconjugates are capable of killing antigen-negative cancer cells through radiation crossfire sometimes termed the "innocent bystander" effect. Both types of immunoconjugates are able to deliver therapy to specific sites of disease while limiting systemic exposure to the chemotherapy agent or radiation.

Finally, MoABs have been developed that target the underlying mechanism of cell growth and proliferation. These agents are discussed later in the chapter but have similar structure, nomenclature, and potential adverse effects as agents that target antigens present on malignant cells.

MONOCLONAL ANTIBODIES THAT TARGET CELL SURFACE GLYCOPROTEINS

Gemtuzumab Ozogamicin

Gemtuzumab ozogamicin consists of a recombinant humanized anti-CD33 MoAB conjugated to the calicheamicin derivative *N*-acetyl-gamma calicheamicin, a cytotoxic antitumor antibiotic, by the linker ozogamicin.[44,46] The myeloid cell-surface antigen CD33 is expressed on the surface of leukemic blasts in more than 80% of patients with acute myelogenous leukemia.[44,46] The binding of the Fab fragment of gemtuzumab ozogamicin to the CD33 antigen results in the formation of a complex that is internalized into $CD33^+$ cells. Upon internalization, the calicheamicin derivative is cleaved from the antibody and released inside the cell. The released calicheamicin derivative binds to DNA in the minor groove resulting in DNA double-strand breaks and cell death.[46,50]

Gemtuzumab ozogamicin was indicated in elderly patients with $CD33^+$ acute myelogenous leukemia and who have failed at least one chemotherapy regimen. Gemtuzumab has been voluntarily withdrawn from the United States market because of concerns over efficacy and safety. Some of the adverse events reported with gemtuzumab ozogamicin are myelosuppression, tumor lysis syndrome, and hepatotoxicity. Myelosuppression is the most severe toxicity associated with gemtuzumab ozogamicin.[44,51] Tumor lysis syndrome including secondary renal failure secondary has been reported in association with the use of gemtuzumab ozogamicin. Leukoreduction with hydroxyurea or leukapheresis prior to administration of gemtuzumab ozogamicin and appropriate preventive measures may be considered to decrease the likelihood of tumor lysis syndrome. Hepatotoxicity, including severe venoocclusive disease, has also been reported in association with the use of gemtuzumab ozogamicin.[50,51] Risk factors include receiving gemtuzumab before or after hematopoietic stem cell transplantation, underlying hepatic disease or abnormal liver function, and patients receiving gemtuzumab ozogamicin in combination with chemotherapy.

Rituximab

Rituximab was the first MoAB approved as an anticancer agent by the FDA (November 1997). Rituximab is a chimeric MoAB directed against the CD20 antigen found on the surface of normal and malignant B cells.[52] The Fab domain of Rituximab binds to the CD20 antigen on B lymphocytes and the Fc domain recruits immune effector functions to mediate B-cell lysis.[52] Possible explanations for its antitumor effect include CDC- and ADCC-mediated killing of malignant B cells along with a direct apoptotic effect.[52]

Rituximab is approved for the treatment of patients with relapsed or refractory, low-grade or follicular, CD20-positive, B-cell non-Hodgkin's lymphomas and as first-line therapy for patients with aggressive and indolent non-Hodgkin lymphomas in combination with chemotherapy. It is also approved for use in patients with other malignancies with CD20-antigen expression (e.g., chronic lymphocytic leukemia) in combination with standard chemotherapy.[52,53] Rituximab is also approved for the treatment of refractory rheumatoid arthritis and has an evolving role in a variety of immune-mediated diseases such as Waldenström macroglobulinemia, aplastic anemia, and others.

Most of rituximab's adverse events occur during the first infusion and are components of an infusion-related complex secondary to the amount of circulating B cells. After the first infusion, the incidence and the severity of these reactions decrease dramatically.[52,53] The most common events in the infusion-related complex are transient fever, chills, nausea, asthenia, and headache. Infection and severe hematologic events with rituximab are infrequent with neutropenia, anemia, and thrombocytopenia occurring in less than 1% of patients.[52]

Ibritumomab Tiuxetan

Ibritumomab tiuxetan is an immunoconjugate that consists of the murine anti-CD20 MoAB ibritumomab and tiuxetan, a linker-chelator, that allows the attachment of indium-111 (used for imaging and dosimetry) and yttrium-90 (active radiotherapy).[55] The ibritumomab therapeutic regimen consists of two steps.[50,55] Y-90–ibritumomab is the therapeutic radiation isotope and selectively delivers radiation to B cells that express the CD20 antigen.

The radiation-induced cytotoxicity delivered by Y-90–ibritumomab not only affects the tumor cells it binds to, but also other cells that are within the pathlength of the radioisotope's emissions (innocent bystander effect).[49,50,55] Consequently, Y-90–ibritumomab can induce cell death in CD-20–positive and –negative tumors and eradicate a large number of tumor cells. Ibritumomab also induces ADCC, CDC, and apoptosis in target cells.[49,50,55]

Ibritumomab tiuxetan is indicated for the treatment of relapsed or refractory low-grade, follicular, or transformed B-cell non-Hodgkin lymphoma, including rituximab-refractory non-Hodgkin lymphoma. Because ibritumomab is derived from murine sources, only one course of therapy is recommended to prevent the development of HAMA reactions.

Adverse reactions associated with the ibritumomab tiuxetan treatment regimen include severe infusion-related reactions, including life-threatening anaphylaxis.[49,50,55] Unlike rituximab, myelosuppression is common with ibritumomab as a consequence of the radioisotope component of the antibody.[49,55] Ibritumomab tiuxetan results in prolonged thrombocytopenia and neutropenia and dose modifications are necessary based on baseline neutrophil and platelet blood counts.[55] The median durations of thrombocytopenia and neutropenia were 24 and 22 days, respectively, and monitoring and management of cytopenias, along with their complications (e.g., febrile neutropenia, bleeding) is necessary for up to 3 months after the completion of treatment.[50,55]

Tositumomab

Tositumomab is another murine anti-CD20 radioimmunoconjugate, similar to ibritumomab. One important difference is that tositumomab is combined with the radioisotope iodine I-131 which has therapeutic and safety implications. The tositumomab therapeutic regimen also consists of two steps.[49] The mechanisms of cell death are similar to ibritumomab as is the indication for use in patients with refractory non-Hodgkin lymphoma.

Most adverse effects are similar to ibritumomab with infusion-related reactions requiring appropriate premedications along with prolonged myelosuppression, primarily neutropenia and thrombocytopenia. Complete blood counts should be obtained weekly for 10 to 12 weeks to assess recovery of normal blood counts. To prevent iodine uptake by the thyroid gland, and subsequent delivery of ionizing radiation to the thyroid gland, thyroid protective agents such as saturated solution of potassium iodide should be initiated prior to the start of the tositumomab regimen and continued for 14 days after the therapeutic dose.[49,56]

Alemtuzumab

Alemtuzumab is a recombinant humanized MoAB that is directed against CD52. CD52 is expressed on the surface of B and T lymphocytes, natural killer cells, monocytes, and macrophages.[57] Alemtuzumab's therapeutic effect comes from binding to the CD52 antigen present on leukemic lymphocytes in chronic lymphocytic leukemia and inducing cell lysis and death.[57]

Alemtuzumab is indicated for the treatment of B-cell chronic lymphocytic leukemia in patients who have been treated with alkylating agents and who have failed fludarabine therapy. It is also being investigated as part of conditioning regimens for hematopoietic stem cell transplants, treatment of autoimmune hematologic disorder, indolent non-Hodgkin lymphomas, and treatment of graft-versus-host disease.[50,57]

Alemtuzumab is associated with severe infusion-related reactions, hematologic toxicity, and opportunistic infections that are severe enough to warrant a black box warning in the package insert.[44,57] Hematologic toxicity consisting of severe prolonged neutropenia and thrombocytopenia occur in most patients. Clinicians should monitor blood counts prior to alemtuzumab administration to determine if the dose needs to be delayed or reduced.[44,50,57]

Because CD52 is expressed on lymphocytes, alemtuzumab can induce profound lymphopenia including a decrease in CD4 and CD8 counts.[44,50,57] Patients should receive prophylaxis for *Pneumocystis jirovecii* pneumonia and herpes virus which should be continued for up to six months after alemtuzumab therapy or until recovery of CD4 counts to prevent complications.[44,57]

AGENTS THAT TARGET GROWTH FACTOR RECEPTORS AND LIGANDS

Recent advances in molecular biology have identified a number of pathways and potential targets related to cancer cell growth and survival. Targeting the HER pathway is currently used to treat a variety of solid tumor malignancies. MoABs have been developed to target the extracellular receptors of the HER family. In addition, small molecular inhibitors that target intracellular signal transduction pathways are available to clinicians for several malignancies. Additional agents target the vascular endothelial growth factor (VEGF) ligand or receptor and other downstream signaling targets.

7 As mentioned previously, the HER family of receptors contains four known members, which upon binding to growth factor ligands result in intracellular phosphorylation of transcription factors and cell proliferation (Fig. 135–8).[9,58,59] HER-1 (more commonly called EGFR) and HER-2 are known to be overexpressed in several cancers, including breast, lung, and colon cancers.

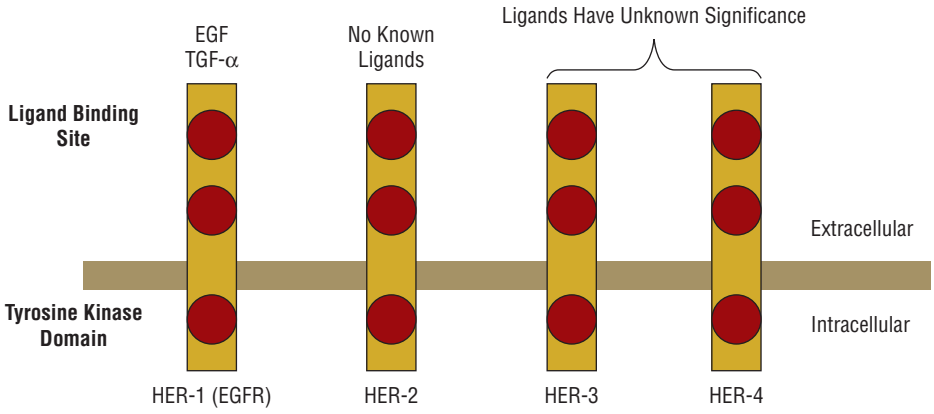

FIGURE 135-8. The HER family of growth factor receptors. All members of the human epidermal growth factor receptor (HER) contain a transmembrane glycoprotein, an extracellular ligand binding site, and a hydrophobic intracellular portion with a tyrosine kinase domain. HER-1 (or more commonly called EGFR [epidermal growth factor receptor]) has several known ligands (commonly implicated in cancer are EGF [epidermal growth factor] and TGF-α [transforming growth factor-α]); HER-2 has no known ligands; while the significance of ligands for HER-3 and HER-4 are unknown at this time. Once the molecule binds to another member of the HER family the tyrosine kinase domain is phosphorylated and genes regulating proliferation, antiapoptosis, and cell transformation are turned on.

Activation of these receptors leads to uncontrolled cellular growth and proliferation, tumor metastasis, and the prevention of apoptosis in malignant cells.[58] The roles of HER-3 and HER-4 in cancer growth and proliferation are still under investigation. All members of this family contain a transmembrane glycoprotein extracellular ligand binding site, a transmembrane domain, and a cytosolic tyrosine kinase tail. Members of the HER family are inactive by themselves, and must form a dimer (a molecule composed of two subunits), either with a member of the same family (homodimer), or with a member of a different subtype of the HER family (heterodimer).[59] Dimerization of the receptor leads to tyrosine kinase phosphorylation and subsequent activation of downstream pathways required to activate signal transduction and cell growth.

Based on these identified cellular targets, several agents have been developed to prevent signal transduction through this pathway. MoABs which competitively bind to extracellular receptors of the HER family and prevent ligand binding and subsequent dimerization of receptors are available to clinicians. In addition, small molecules that target intracellular tyrosine kinase receptors are approved for use in a variety of tumors. These agents allow growth factor receptors to dimerize but prevent the phosphorylation of tyrosine kinase domains. The net effect of both strategies is to prevent downstream activation of the signal transduction resulting in a decrease in cell proliferation (Fig. 135–9).

Human Epidermal Growth Factor Receptor Family

Cetuximab and Panitumumab Cetuximab is a chimeric MoAB that binds specifically to the extracellular domain of EGFR.[44,46,60] Cetuximab binds to EGFR on both normal and tumor cells and competitively inhibits the binding of epidermal growth factor and other ligands, such as transforming growth factor-α.[46,60] Binding of cetuximab to the EGFR results in inhibition of cell growth, induction of apoptosis, and inhibition of VEGF production. Cetuximab is primarily given as monotherapy or in combination with other anticancer agents in the treatment of metastatic colorectal cancer.[60,61] Cetuximab is also approved for use in head and neck cancer either by itself or in combination with radiation.[62]

The most serious adverse events associated with cetuximab are infusion-related reactions and development of an acne-like rash.[44,61,63] Skin reactions occur in most patients receiving cetuximab and can be severe. This reaction is similar between all EGFR inhibitors regardless of the site of action (extracellular or intracellular) and appears to be related to the function of EGFR in skin follicles.[64] Skin reactions appear most commonly on the face, upper chest, and back, but can extend to the extremities. These reactions are characterized by multiple follicular or pustular appearing lesions that generally appear within the first 2 weeks of therapy. Although the reactions usually resolve following cessation of treatment, resolution can be slow, continuing beyond 28 days in nearly one half of cases. In patients who develop severe rash, dose modifications may be necessary. Interestingly, a trend for improved responses with increasing severity of skin reactions has been reported and requires further follow-up to assess the clinical importance of these reactions.[61,64] Other common adverse events with cetuximab include fatigue, gastrointestinal complaints (nausea, vomiting, diarrhea, and constipation), and abdominal pain.[61]

Panitumumab is a MoAB that also binds to the cell surface EGFR. It is an IgG2 antibody, and the first fully human MoAB approved to treat cancer.[65] Panitumumab is approved as a single agent in refractory metastatic colon cancer. Adverse reactions are similar to cetuximab though severe reactions appear to be rare because it does not have a murine component.[65]

Trastuzumab Trastuzumab is a humanized MoAB that selectively binds to HER-2.[53,56] HER-2 is overexpressed in about one third of patients with breast cancer and to varying degrees in a variety of other malignancies (e.g., ovarian, lung, prostate).[9,53] Trastuzumab inhibits cell-cycle progression by decreasing cells entering the S phase of the cell cycle, leading to downregulation of HER-2 receptors on tumor cells and decreased cell proliferation.[66] Trastuzumab also leads to ADCC and CDC, along with

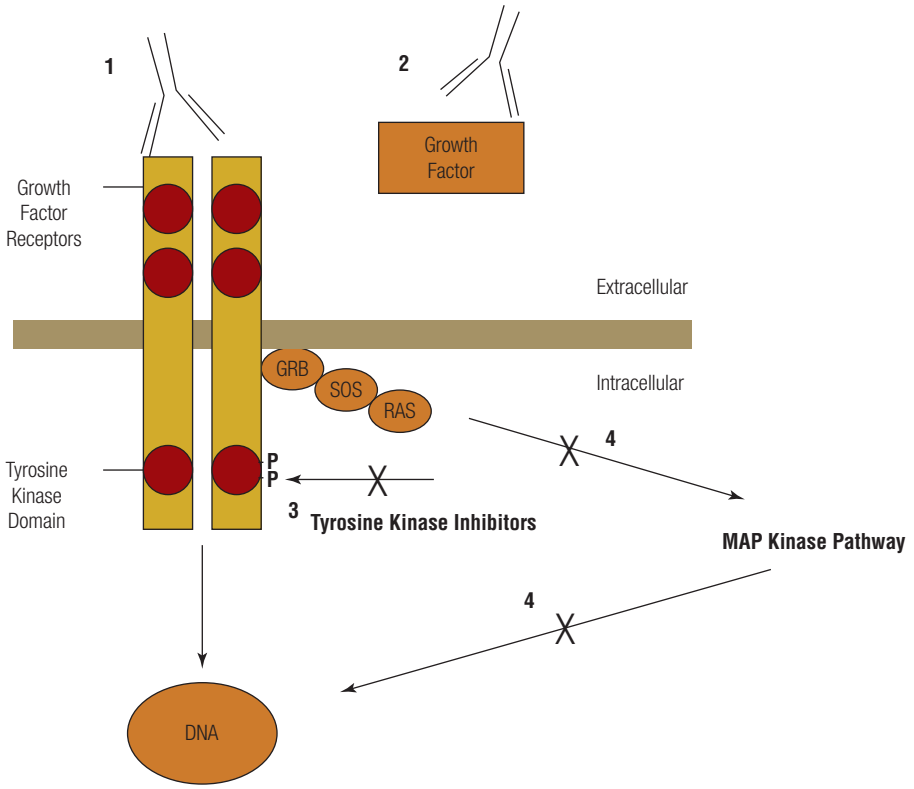

FIGURE 135-9. Strategies against growth factor receptors include (1) MoABs against the growth factor receptor; (2) MoABs against the growth factor itself; (3) molecules that target intracellular tyrosine kinases and prevent phosphorylation of tyrosine residues and subsequent activation of downstream signals; and (4) targeting downstream signals such as the MAP (mitogen activation protein) kinase pathway. All of these targets have the same goal of decreasing cell proliferation and increasing cell death of tumor cells.

directly inducing apoptosis in cells overexpressing the HER-2 protein.[66] In addition, synergy between trastuzumab and traditional chemotherapeutic agents has been demonstrated, resulting in trastuzumab often being used in combination with traditional chemotherapy agents.

Trastuzumab is approved in the treatment of metastatic breast cancer as a single agent or in combination with paclitaxel. Trastuzumab has also demonstrated a benefit in the adjuvant treatment of HER-2 positive breast cancer and is given for 1 year in combination with chemotherapy.[67] The combination of trastuzumab with other chemotherapy agents including vinorelbine, carboplatin, and others has shown synergistic effects and is under clinical investigation.[53] The addition of trastuzumab to anthracycline therapy is not recommended because of concerns of additive cardiotoxicity.

Trastuzumab is administered as a loading dose followed by weekly infusions as a single-agent or in combination with chemotherapy.[66] Trastuzumab has been administered every 3 weeks in combination with various chemotherapy agents to simplify the chemotherapy regimen; response rates and safety appear similar to those seen in the approved weekly trastuzumab regimen.[68]

The most serious adverse reactions caused by trastuzumab include cardiomyopathy, infusion-related reactions, hypersensitivity reactions (including anaphylaxis), and increased myelosuppression. An evaluation of cardiac function should be performed prior to administration and extreme caution should be exercised in patients with preexisting cardiac dysfunction and in those who have received prior anthracyclines. In patients who develop a clinically significant decrease in left ventricular function (ejection fraction <50% or greater than 10% decrease), discontinuation of therapy should be considered. Similar to most MoABs, the symptoms associated with a hypersensitivity reaction are most common with the initial infusions of trastuzumab and occur infrequently thereafter.

Myelosuppression is infrequent following the administration of trastuzumab as a single agent, but the incidence of neutropenia and febrile neutropenia is higher when trastuzumab is given with myelosuppressive chemotherapy as compared to giving the chemotherapy alone.[66]

Erlotinib Erlotinib is an orally active, selective EGFR-tyrosine kinase inhibitor that blocks signal transduction pathways involved in proliferation, survival, and metastases of cancer cells.[69,70] It inhibits EGFR activity by competing with adenosine triphosphate for its binding site on the EGFR tyrosine kinase cytosolic domain, which blocks the tyrosine kinase cascade of downstream signaling, and ultimately interferes with the proliferation and growth of cancer cells.

Erlotinib is indicated for the treatment of patients with locally advanced or metastatic non-small-cell lung cancer as a second-line agent.[70] Erlotinib is also approved for use in pancreatic cancer in combination with gemcitabine. Erlotinib has also demonstrated activity in a variety of other tumors such as head and neck and brain tumors.

Rash and diarrhea are the most common adverse events reported with erlotinib. Some studies suggest that the development of a rash may be predictive of a response to therapy and correlates with clinical benefit.[64] The rash that develops is similar to cetuximab and is treated similarly. Interstitial lung disease is a rare adverse effect reported in patients taken erlotinib. Drug interactions include increased international normalized ratio for patients on concomitant warfarin and increased or decreased erlotinib drug levels with inhibitors or inducers of CYP3A4, respectively.

Lapatinib Lapatinib is a small molecule 4-anilinoquinazoline kinase inhibitor that inhibits the intracellular kinase domains of both EGFR and HER-2.[72] It has demonstrated clinical activity in combination with capecitabine in breast cancer patients who have overexpression of HER-2 and who have previously received therapy with trastuzumab, an anthracycline and a taxane.[72] Toxicity for lapatinib was notable for an increased incidence of diarrhea, hepatoxicity, rash, and QT interval prolongation. Lapatinib has significant CYP450 mediated drug–drug interactions.

Vascular Endothelial Growth Factor

8 Angiogenesis, the development of new blood vessels, is a process important for normal physiologic processes but becomes unregulated in several malignancies and can lead to tumor growth, invasion, and metastasis. This process is regulated by pro- and antiangiogenic growth factors, which are released in response to hypoxia and other stresses to the cell.[80] Proangiogenic growth factors include VEGF, fibroblast growth factors, platelet-derived growth factor, tumor necrosis factor-α, and keratinocyte growth factor. Antiangiogenic growth factors include interleukin (IL) 12, interferons, platelet factor 4, and tissue inhibitors of metalloproteinase.[73]

The best studied proangiogenic factor is VEGF, whose elevated levels have been associated with a poor prognosis and an increased risk of metastases in a variety of malignancies, including acute myeloid leukemia, breast cancer, hepatocellular carcinoma, non-small cell lung cancer, ovarian cancer, and colon cancer.[73] Similar to other growth factors, VEGF binds to specific receptors located on the extracellular domain of growth factor receptors. Three known receptors of VEGF have been identified: VEGFR-1, −2, and −3.[73] The VEGFR-1 and VEGFR-2 receptors are expressed primarily in endothelial cells and in some tumor cells, and mediate the biologic effects of VEGF. Each of the receptors induces a different signal transduction pathway. These pathways eventually result in the generation of proteases that are necessary for the breakdown of the extracellular matrix, the first step of angiogenesis. Interference with their ability to develop new blood vessels by means of antiangiogenic agents can limit or prevent tumor growth.[73]

Anticancer agents can interfere with angiogenesis in many different ways. Examples are targeting vascular growth factors, or the production and control of the endothelial cells that make up the vessel linings. Most antiangiogenic agents are cytostatic rather than truly cytotoxic, as they prevent new vessel growth and thus cause growth delay of the tumors. Some vascular targeting agents, however, can destroy existing blood vessels and may have cytotoxic properties.[73]

Bevacizumab Bevacizumab is a humanized MoAB directed against circulating VEGF.[73] It binds to all biologically active circulating isoforms of VEGF and prevents the activation and promotion of angiogenesis.[73]

Bevacizumab is approved, in combination with 5-FU–based chemotherapy, for the initial treatment of metastatic colorectal cancer[74] and for first-line treatment, in combination with carboplatin and paclitaxel, of patients with unresectable, locally advanced, recurrent or metastatic nonsquamous non-small cell lung cancer. Additional FDA approved uses include breast, renal cell, and glioblastoma malignancies with off-labeled use in ovarian, pancreatic, head and neck, and cervical cancers.

The three most frequent adverse effects associated with bevacizumab are hypertension, bleeding episodes, and thrombotic events.[74,75] Hypertension associated with bevacizumab is more common in patients with a previous history of hypertension and responds to oral antihypertensive medications. The most common type of bleeding associated with bevacizumab is transient nosebleeds. However, fatal CNS and gastrointestinal hemorrhages have been reported. The manufacturer has issued a black box warning regard-

ing the risk of gastrointestinal perforation, wound dehiscence, and fatal hemoptysis.[75] Bevacizumab is not recommended for use within 28 days of major surgery and patients should be instructed to report abdominal pain (an initial sign of gastrointestinal hemorrhage) to their healthcare provider immediately. Paradoxically, bevacizumab also has been found to cause thrombotic events, including deep vein thrombosis, pulmonary embolism, and myocardial infarction, especially in elderly patients with a history of cardiac events. Another rare adverse effect associated with bevacizumab is proteinuria and patients should be monitored for the development or worsening of proteinuria by checking urine dipsticks for protein. Patients with a 2+ or greater urine dipstick reading should undergo further assessment to determine if bevacizumab is safe to administer.

Sunitinib and Sorafenib Most targeted agents approved to date have been developed against a single target associated with either the tumor or its growth and survival. Two similar agents—sunitinib and sorafenib—inhibit multiple tyrosine kinases, with the goal of enhanced antitumor activity. These agents are inhibitors of VEGFR-2 and platelet-derived growth factor receptor, which are involved in angiogenesis; c-KIT involved in gastrointestinal stromal tumors; and FLT3 involved in leukemia. In addition, sorafenib inhibits several isoforms of the serine/threonine kinase Raf, which is part of the mitogen-activated protein kinase-signaling pathway involved in cell proliferation.[76]

Gastrointestinal adverse effects such as diarrhea are common with both agents, as is rash, fatigue, and hypertension. Unique adverse events include congestive heart failure with sunitinib and hand–foot syndrome with sorafenib.

Both of these agents are approved for use in advanced renal cell cancers and sunitinib is also approved for gastrointestinal stromal tumors after imatinib failures. Ongoing trials are evaluating both of these agents in other tumors.

MISCELLANEOUS BIOLOGIC AND TARGETED AGENTS

Imatinib, Dasatinib, and Nilotinib

Imatinib is a selective inhibitor of the tyrosine kinase activity of BCR-ABL fusion gene, the product of the Philadelphia chromosome.[77] The Philadelphia chromosome is the hallmark finding of chronic myeloid leukemia and is a translocation of genetic material between chromosomes 9 and 22. Imatinib binds to the kinase binding site of the BCR-ABL gene, competitively blocking access to adenosine triphosphate. This prevents tyrosine-kinase phosphorylation of the gene and downstream activation of cellular proliferation.[84] Imatinib also causes apoptosis or arrest of growth in hematopoietic cells expressing BCR-ABL. An additional effect of imatinib is its ability in blocking the tyrosine kinase activity of c-KIT (stem-cell factor receptor) and platelet-derived growth factor receptor.[46,77]

Imatinib is a standard treatment option for newly diagnosed Philadelphia chromosome-positive (Ph^+) chronic myeloid leukemia and for c-KIT (CD117)-positive gastrointestinal stromal tumors. A major advance observed with imatinib therapy is its ability to eliminate the Philadelphia chromosome in patients receiving therapy resulting in cytogenetic responses (elimination of the genetic defect), thus achieving the goal of all targeted therapies; the attack and elimination of the underlying cancer biology.

Adverse effects to imatinib are usually mild to moderate in severity. Severe fluid retention (pleural effusion, pericardial effusion, and ascites) occurs in less than 10% of patients taking imatinib. Patients should be monitored regularly for early signs and symptoms of fluid retention (leg swelling, shoes no longer fitting, and shortness of breath) and instructed to call their healthcare clinicians when symptoms first develop. Additional adverse effects for imatinib include mild or moderate superficial edema, elevation of liver enzymes, nausea, muscle cramps, headache, and rash.[78] Rash may require early intervention as rare cases of Stevens-Johnson syndrome have been reported with imatinib and may require permanent discontinuation of therapy.[78]

Imatinib is metabolized by and is an inhibitor of the CYP3A4 enzyme system and caution should be exercised when substrates, inducers, or inhibitors of CYP3A4 are used concomitantly with imatinib.[78] Imatinib is also an inhibitor of CYP2D6 and levels of CYP2D6 substrates can increase.

Dasatinib and nilotinib are next-generation tyrosine kinase inhibitors that share the same binding site on the BCR-ABL tyrosine kinase adenosine triphosphate-binding domain with imatinib.[79] In contrast, dasatinib and nilotinib maintain clinical activity in chronic myeloid leukemia patients with mutations in the BCR-ABL binding site that confer imatinib resistance with the exception of one polymorphism (T135I) in which all three anticancer agents appear resistant. Nilotinib and dasatinib received FDA-approval for the treatment of patients with chronic myeloid leukemia resistant or intolerant to imatinib. Nilotinib and dasatinib recently received FDA approval for first-line treatment of newly diagnosed chronic myeloid leukemia. Dasatinib also inhibits a family of tyrosine kinases called SRC kinases that are believed to mediate cellular differentiation, proliferation, and survival; SRC kinases have been implicated in modulating multiple oncogenic signal transduction pathways.[84]

Dasatinib and nilotinib have a toxicity profile similar to that of imatinib with myelosuppression, nausea and vomiting, headache, and fluid retention being commonly reported. Dasatinib has also been reported to cause hypocalcemia and pleural effusions. Similar to other tyrosine kinase inhibitors, these anticancer drugs have extensive drug–drug interactions with substrates, inducers and inhbitors of CYP3A4, as well as other CYP enzymes.

Bortezomib

The proteasome is an enzyme complex that is responsible for degrading proteins that control the cell cycle. Some of the proteins degraded by proteosomes regulate critical functions for cancer growth, such as regulation of the cell cycle, transcription factors, apoptosis, angiogenesis, and cell adhesion.[80] One proteosome inhibitor, bortezomib, is commercially available. Bortezomib has very specific affinity for the catalytic portion of the proteosome. It can induce apoptosis in cancer cells indirectly. Bortezomib is a specific inhibitor of the 26S proteasome; one consequence of 26S proteasome inhibition is the accumulation of IκB, an inhibitor of the major transcription factor NF-κB. NF-κB induces transcription of genes that block cell death pathways and promote cell proliferation. Its activity depends on its release from its inhibitory partner protein, IκB, in the cytoplasm and move to the nucleus. When IκB fails to degrade, through the actions of bortezomib, NF-κB remains in the cytoplasm, preventing it from transcribing the genes that promote cancer growth. Bortezomib is approved for the treatment of patients with multiple myeloma and mantle cell lymphoma.[80]

The most commonly reported adverse events are asthenia (fatigue, malaise, and weakness), nausea, and diarrhea occurring in over half of patients. Additional adverse effects include decreased appetite, nausea, constipation, myelosuppression, peripheral neuropathies, and fever.[80] Most of these adverse effects are mild to moderate and managed with supportive care measures. Of these common adverse effects, severe adverse effects were limited to thrombocytopenia, neutropenia, asthenia, and peripheral neuropathies. Bortezomib is administered every 72 hours to minimize cumulative toxicity, by permitting the restoration of proteasome function between doses.

Temsirolimus and Everolimus

Mammalian target of rapamycin (mTOR) is a component of intracellular signaling pathways involved in the growth and proliferation of cells. mTOR receives input from upstream signaling pathways, including growth factors and hormones. Once activated, mTOR stimulates protein synthesis by phosphorylating translation regulators. mTOR also contributes to protein degradation and angiogenesis.[81]

Temsirolimus binds to FKBP-12 and the protein–drug complex inhibits the activity of mTOR by blocking its kinase activity.[81] mTOR inhibition suppresses the production of proteins that regulate progression through the cell cycle and angiogenesis. mTOR inhibition also results in reduced levels of cell growth factors involved in angiogenesis such as VEGF. Temsirolimus is approved for metastatic renal cell carcinoma, in which angiogenesis is a prominent clinical feature.

The most common adverse reactions with temsirolimus are rash, fatigue, mucositis, nausea, edema, and loss of appetite. The most common laboratory abnormalities are increases in serum creatinine and liver function tests, thrombocytopenia, and neutropenia. Additionally, hyperglycemia and hyperlipidemia that require monitoring of glucose and lipid profiles should be expected.[81] Rare, but potentially serious adverse effects include interstitial lung disease, immunosuppression (and infection), and renal failure. Temsirolimus is metabolized by CYP3A4, and possible drug interactions requiring dosage adjustments may be necessary.

Everolimus is an oral inhibitor of mTOR that is approved for the treatment of patients with advanced renal cell carcinoma after failure of treatment with sunitinib or sorafenib.[81] Adverse reactions and potential drug interactions are similar to temsirolimus.

Thalidomide and Lenalidomide

Thalidomide, the infamous drug that caused severe limb deformities (phocomelia or "seal limbs") when used by pregnant women as a nonprescription sedative in the 1960s, is approved for treatment of leprosy and has orphan drug status for multiple myeloma. It also has documented clinical activity in several other types of cancer. Thalidomide is a glutamic acid derivative, and is broadly classed as an immunomodulatory agent. Lenalidomide, is a novel 4-aminoglutarimide analog of thalidomide with similar therapeutic activity, but a different adverse effect profile.[82] These agents have many potential mechanisms of action, with the main hypothesis thought to be through angiogenesis inhibition, an action also linked to its teratogenic effects. Other possible mechanisms include direct inhibition of cancer cells, free radical oxidative damage to DNA, interfering with adhesion of cancer cells, inhibiting tumor necrosis factor-production, or altering secretion of cytokines that affect the growth of cancer cells.[82]

The most common adverse events for thalidomide include somnolence, constipation, dizziness, orthostatic hypotension, rash, and peripheral neuropathies. Neutropenia is extremely rare. In contrast, lenalidomide is associated with much less somnolence and neuropathies compared to thalidomide.[82] Neutropenia, thrombocytopenia, and thrombotic issues are most prevalent with lenalidomide use. Because thalidomide is teratogenic, great care must be taken to prevent their use during pregnancy and several members of the healthcare team are required by the FDA to assist in this goal. All pharmacies and prescribers must be enrolled in the System for Thalidomide Education and Prescribing Safety (S.T.E.P.S.) program to dispense thalidomide and lenalidomide is only available under a special restricted distribution program called RevAssist.

Retinoids

Vitamin A and its metabolites, collectively referred to as the retinoids, play important roles in numerous biologic processes, including normal cellular differentiation. Because cancerous growth is characterized by abnormal cellular differentiation, retinoids may play important therapeutic roles in the treatment and perhaps in the prevention of cancers. Tretinoin (all-*trans*-retinoic acid) is a naturally occurring derivative of vitamin A (retinol). Other retinoids indicated for treatment of cancers include alitretinoin (9-*cis*-retinoic acid), available in gel form for topical management of Kaposi sarcoma lesions, and bexarotene (Targretin) gel or capsules for treatment of cutaneous T-cell lymphoma.[18,83]

Retinoids are classed as morphogens, small molecules released from one type of cell that can affect the growth and differentiation of neighboring cells. Their normal roles in the human body are to induce differentiation of some cells, stop the differentiation of others, and both suppress and induce apoptosis in different cell types. Their diverse actions come from the diversity of their receptors. The two classes of retinoid receptors are retinoid X receptors (RXRs) and retinoic acid receptors (RARs), each with α, β, and γ subclasses. RXRs are versatile; they bind to RARs and to other nuclear receptors such as thyroid hormone receptors. Once activated, the receptors act as transcription factors that, in turn, regulate the expression of genes that control cellular growth and differentiation.[18,83]

Tretinoin binds primarily to the RAR-α receptors. Alitretinoin is considered a panagonist, which means that it binds to all known retinoid receptors, producing diverse regulatory effects. Bexarotene is synthetic and is classed as a rexinoid. It is the first RXR-selective retinoid agonist. The exact mechanism of action of alitretinoin and bexarotene as anticancer agents is unknown.[18,83]

Interferons

The interferons (IFNs) are a family of proteins produced by nucleated cells and by recombinant DNA technology, with antiviral, antiproliferative, and immunoregulatory activities. They are classified as α, β, or γ interferons based on antigenic, biologic, and pharmacologic properties. Many subtypes of IFN-α are known. IFN-α_{2a} and IFN-α_{2b}, approved for anticancer indications, are very similar single-species recombinant products.

The mechanisms of IFN-α's antitumor action are complex. IFN increases the activity of cytotoxic cells within the immune system, but they also have direct antiproliferative effects. IFNs prolong the cell cycle, which results in cytostasis, an increase in cell size, and apoptosis. They can inhibit new blood vessel formation in tumors and can increase the expression of antigens on tumor cell surfaces, making the cancerous cells more easily recognized by immune effector cells. They also inhibit or block certain oncogenes that can direct the unregulated cell growth that is characteristic of cancerous cells. Alterations in gene expression may change the levels of receptors for other cytokines, or the concentration of regulatory proteins on immune cells, or may activate enzymes that alter cellular growth and function.[84]

The most frequent adverse effects are flu-like symptoms. Other adverse events include psychiatric symptoms (e.g., depression, anxiety), insomnia and sleep disturbances, myelosuppression, and alopecia.

Interleukin-2 (Aldesleukin)

Interleukin-2 (IL-2) is a cytokine produced by recombinant DNA technology that promotes B- and T-cell proliferation and differentiation and initiates a cytokine cascade with multiple interacting immunologic effects. The IL-2 receptor is expressed in increased amounts on activated T cells and mediates most of the effects of aldesleukin. Antitumor effects depend on proliferation of cytotoxic immune cells that can recognize and destroy tumor cells without damaging normal cells. Some of these cytotoxic cells are natural killer cells, lymphokine-activated killer (LAK) cells, and tumor-infiltrating lymphocytes.[85]

The toxicity of aldesleukin is related to dose, route, and duration of therapy, but aldesleukin is toxic therapy that requires vigorous supportive care. The most common dose-limiting toxicities are hypotension, fluid retention, and renal dysfunction. Aldesleukin decreases peripheral vascular resistance, producing peripheral vasodilation, tachycardia, and hypotension. A characteristic vascular- or capillary-leak syndrome produces fluid retention, which, in turn, can cause respiratory compromise. These toxicities require administration of vasopressors in most patients, judicious use of fluid support and diuretics, and supplemental oxygen. Patients with underlying cardiovascular or renal abnormalities are more susceptible to these adverse effects, making careful patient selection important.[85] Most patients treated with aldesleukin experience thrombocytopenia, anemia, eosinophilia, reversible cholestasis, and skin erythema with burning and pruritus, and some have neuropsychiatric changes, hypothyroidism, and bacterial infections.[85] In general, the toxicities from aldesleukin therapy reverse quickly once therapy is stopped, and can be managed or prevented by careful prospective monitoring and pharmacologic supportive care.

Denileukin Diftitox

Denileukin diftitox is a recombinant fusion protein that combines the active sections of both IL-2 and diphtheria toxin. Unconjugated diphtheria toxin is much too toxic to administer to humans. As the "payload" of the fusion protein, however, its cytotoxic effects are directed toward cells that express the high-affinity form of the IL-2 receptor, such as cancer cells of some patients with cutaneous T-cell lymphoma. Once denileukin diftitox interacts with the IL-2 receptors, the toxin inhibits protein synthesis in the cancer cells and causes cell death.[86]

Although denileukin diftitox is directed therapy, its targeting of cells that express high-affinity IL-2 receptors is not specific because these receptors are expressed on cells other than cancer cells. Denileukin diftitox produces acute hypersensitivity reactions, flu-like symptoms, sometimes with prominent diarrhea, and vascular-leak syndrome. It differs from the vascular-leak syndrome produced by high-dose aldesleukin in that it occurs in fewer patients, is delayed in onset, is usually self-limited, and does not consistently recur on retreatment.[85,86] Patients with an albumin less than 3 g/dL (30 g/L) are at increased risk for vascular-leak syndrome and use in these patients is not recommended.

RESPONSE CRITERIA

The response to anticancer agents and other treatment modalities may be described as a cure, complete response, partial response, stable disease, or progression.[87] A cure implies that the patient is entirely free of disease and has the same life expectancy as a cancer-free individual. Because of our inability to detect small numbers of tumor cells, we can never be absolutely certain that an individual patient is cured. Cancers that are curable with treatment are characterized by a stable plateau in the survival curve where the risk of relapse is very low. For most of these curable cancers, the survival curve has plateaued by about 5 years. Therefore, patients with one of these curable cancers who are alive 5 years from the time of diagnosis without disease recurrence are often considered "cured" of their cancer. However, patients with some malignancies, such as breast cancer and melanoma, are still at significant risk for relapse after 5 years.

In an attempt to simply and unify response definitions in both clinical practice and published reports, the RECIST (Response Evaluation Criteria in Solid Tumors) criteria were developed in 2000 and revised in 2009.[87] *Complete response* (CR) means complete disappearance of all cancer without evidence of new disease for at least 1 month after treatment. The terms *cure* and *CR* are not synonymous. Although an individual must have a CR to be cured, many individuals who achieve a CR will eventually relapse. A *partial response* is defined as a 30% or greater decrease in the tumor size or other objective disease markers, and no evidence of any new disease for at least 1 month. Overall objective response rates for a given treatment are calculated by adding the CR and partial response rates. *Progressive disease* is defined as a 20% increase in the tumor size or the development of any new lesions while receiving treatment. A patient whose tumor size neither grows nor shrinks by the above criteria is termed to have *stable disease*. Some patients may experience subjective improvement in the symptoms caused by their cancer without a defined response. Although clinically important, this does not indicate an objective response. The term *clinical benefit response* was recently developed to document these subjective responses; it refers to patients who have clinical benefit as measured by decreases in pain or analgesic consumption, or improved quality of life or performance status.

These response definitions are applicable to solid tumors, but diseases such as leukemias and multiple myeloma are not characterized by discrete, measurable masses. Responses in these diseases are measured by elimination of abnormal cells (e.g., return to normal hematology parameters and normal bone marrow in leukemia), return of tumor markers to normal levels (e.g., normal serum protein electrophoresis in multiple myeloma), or improved function of affected organs (e.g., improved renal function after obstructive uropathy). Cytogenetic markers and molecular techniques have an increasingly important role in determining whether all cancer has been truly eliminated. For example, in chronic myelogenous leukemia, the Philadelphia chromosome can be detected by polymerase chain reaction techniques, even when no leukemia is evident in the bone marrow or bloodstream. Patients without evidence of the Philadelphia chromosome are classified as a *complete cytogenetic response*. Measuring cytogenetic responses is increasingly common in patients with known cytogenetic abnormalities and absence of complete cytogenetic responses may predict disease relapse.

Finally, different survival endpoints may be used to assess treatment response. Overall survival is considered as the gold standard but increasing emphasis is being placed on other survival endpoints that consider quality of life. These endpoints include disease-free survival and progression-free survival, which measure the time the patient "survives" free of disease (e.g., cancer) or progression, respectively.

The U.S. FDA publishes guidance for industry to facilitate the drug development process.[88] New therapies must demonstrate a favorable risk benefit ratio in adequate and well controlled clinical trials. Overall survival and symptom improvement is considered an appropriate measure of effectiveness. Accelerated approval promulgated in 1992 supported the approval of therapies intended to treat life-threatening or serious illnesses in which the new therapy demonstrated improvement compared to current therapies or provided therapy in the absence of current therapy, based on surrogate endpoints that are likely to predict clinical benefit. Common surrogate endpoints include disease-free survival, progression-free survival, objective response rates and complete response rates; overall response rate is the most common surrogate endpoint used to support accelerated approval. Biomarkers have not been used as primary endpoints to support approval. A clinical trial following accelerated approval must be conducted with due diligence and demonstrate clinical benefit, or the product may be removed from the market. In the time elapsed from 1990 to 2003, 75% of the new therapies for cancer were approved based on endpoints other than survival.[88]

FACTORS AFFECTING RESPONSE TO CHEMOTHERAPY

These include tumor burden, tumor-cell heterogeneity, drug resistance, dose intensity, and patient-specific factors. The significance of tumor burden was discussed earlier in the Principles of Tumor Growth section. Tumors consist of a heterogeneous population of cell types. Because of the genetic instability of cancer cells as compared to normal cells, mutations commonly occur during cell division. Large tumors have undergone many cell divisions and express multiple cell mutations resulting in genetically varied cell populations.[6,19] In 1979, Goldie and Coldman proposed that these cytogenetic changes were not completely random and were highly associated with the development of the ability of tumors to develop drug resistance.[1,6,19] The probability of developing resistant cell populations increases as tumor size increases. It is believed that a small percentage of resistant cancer cells may survive initial chemotherapy. Resistant populations later proliferate and eventually become the dominant cell types, which may explain the common pattern of an initial response to chemotherapy, followed by progressive tumor regrowth despite continuing the same treatment regimen.

Drug resistance may be either an acquired or inherited property of a cancerous cell. Mechanisms of drug resistance include decreased activation of prodrugs, decreased uptake of drugs secondary to alterations in drug transport systems, changes in target enzymes, alterations in the ability to repair drug-induced damage, increased drug inactivation, and decreased apoptosis.[6,11,19] One focus of research is in the area of multidrug resistance.[19,89] When some cancer cells are exposed to increasing concentrations of a specific anticancer agent in vitro, they become resistant to that agent. Surprisingly, these same cells also become resistant to other structurally unrelated anticancer agents and are therefore considered multidrug resistant. Cytotoxic agents derived from natural products, such as the anthracyclines, actinomycin D, mitomycin C, the vinca alkaloids, the epipodophyllotoxins, and the taxanes, produce multidrug resistance. The resistant cancer cells possess a membrane-associated protein known as Pgp, which appears to enhance the export of toxins, such as chemotherapy agents, out of the cell (Fig. 135–10). The gene that encodes for Pgp is known as the *mdr-1* gene. Expression of this gene is amplified in cells that are resistant to the natural products listed previously. Pgp is also found in high concentrations in tumors that are traditionally resistant to chemotherapy (e.g., renal cell cancer and non-small cell lung cancer) and thus may also be an important mechanism of intrinsic or inherited drug resistance. Several drugs have been investigated as possible inhibitors of this efflux pump, such as the calcium channel blockers, quinidine, cyclosporine, and the phenothiazines. Another efflux pump, known as the multidrug resistance-associated protein (MRP), was also recently identified. Other potential mechanisms of drug resistance include inactivation of chemotherapy agents by glutathione metabolism, upregulation of target enzymes such as topoisomerases or dihydrofolate reductase, and decreased apoptosis after exposure to chemotherapy. The last mechanism can be mediated by *bcl-2* oncogene overexpression or loss of the *p53* gene, as discussed in the oncogene section. The interplay between apoptosis and resistance is an area of intense research.

The relationship between dose and response has been extensively explored in cancer chemotherapy.[1] Dose is believed to be a critical factor in determining response for many types of cancers. *Dose intensity* is defined as the dose delivered to the patient over a specified period of time. The three main variables that determine delivered dose intensity are the dose per course, the interval between doses, and the total cumulative dose. *Dose density* refers

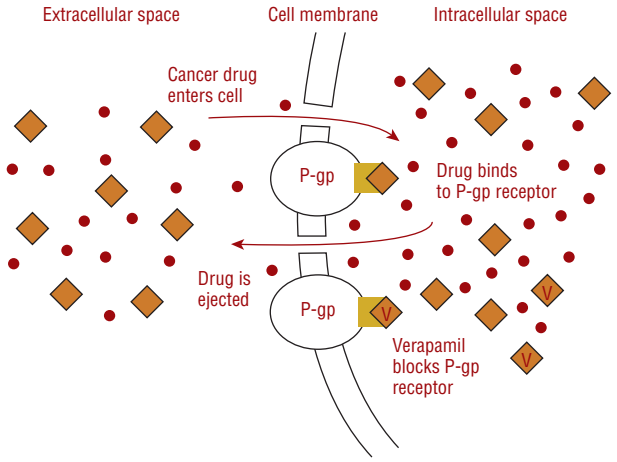

FIGURE 135-10. P-glycoprotein (P-gp) is a membrane-associated protein that acts as a drug efflux pump. Anticancer agents enter the cell, bind to the P-gp receptor, and are ejected. Some agents that modify multidrug resistance, like verapamil, block the P-gp receptor, allowing the anticancer agent to remain in the cell.

to shortening of the usual interval between doses (e.g., every 2 weeks instead of every 3 weeks) and is designed to maximize the drugs' effects on tumor growth kinetics. This strategy has been most extensively studied in breast cancer, with positive results from adjuvant therapy given to patients with high-risk node-positive disease. The delivery of optimal dose intensity is often compromised by the toxicities of the anticancer agent. Treatment cycles are commonly delayed because of inadequate recovery from toxicity, especially myelosuppression. Subsequent doses of chemotherapy are often reduced to prevent or reduce the severity of these toxicities. The impact of this issue on patient outcome has been proven in studies showing reduced rates of response and survival in individuals receiving less-than-optimal chemotherapy doses.[1] Understanding the pathophysiology of toxicities has led to the development of more effective agents for prevention and management of these toxicities. The development of agent- and toxicity-specific chemo protective agents has facilitated application of dose-intensity principles.[1] The colony-stimulating factors avert neutropenia and permit delivery of dose-intensive or dose-dense regimens that are myelosuppressive. The issue of dose intensity is particularly important in the setting of high-dose chemotherapy with autologous hematopoietic stem cell support. Although lethal myelosuppression is avoided by administering hematopoietic stem cells, other severe end-organ toxicities emerge as doses of the anticancer agents are increased.

Patient-specific factors create unpredictable variability in response to chemotherapy. The biology of cancer is strongly affected by host characteristics and genetics. The pathway of genetic mutations that resulted in malignancy can also affect response to therapy. For example, breast cancers that overexpress the HER-2 oncogene are often sensitive to anthracycline-based regimens.[66] Interindividual variations in absorption, distribution, elimination, or metabolism may lead to sub- or supratherapeutic levels of anticancer agents and their metabolites. As a result, both drug efficacy and drug toxicity can be affected. Until recently, healthcare professionals in oncology have modified dose based on variations in body size, blood counts, and renal and hepatic function. Prospective dose modifications based on these parameters are still very important to optimize the effectiveness of therapy and minimize toxicity. But more specific tools are becoming available, as we learn how to identify and apply differences in people's genetic makeup to their anticancer therapy. *Pharmacogenomics* is the study

TABLE 135-10 Performance Status Scales

Description: Karnofsky Scale	Karnofsky Scale (%)	Zubrod Scale (ECOG)	Description: ECOG Scale
No complaints; no evidence of disease	100	0	Fully active, able to carry on all predisease activity
Able to carry on normal activity; minor signs or symptoms of disease	90		
Normal activity with effort, some signs or symptoms of disease	80	1	Restricted in strenuous activity, but ambulatory and able to carry out work of a light or sedentary nature
Cares for self; unable to carry on normal activity or to do active work	70		
Requires occasional assistance but is able to care for most personal needs	60	2	Out of bed more than 50% of time; ambulatory and capable of self-care, but unable to carry out any work activities
Requires considerable assistance and frequent medical care	50		
Disabled; requires special care and assistance	40	3	In bed more than 50% of time; capable of only limited self-care
Severely disabled; hospitalization indicated, although death not imminent	30		
Very sick; hospitalization necessary; requires active supportive treatment	20	4	Bedridden; cannot carry out any self-care; completely disabled
Moribund; fatal processes progressing rapidly	10		
Dead	0

of the role of inheritance in individual variation in drug response.[90] In oncology, several clinically relevant genetic polymorphisms, or variations, have been identified that can affect pharmacokinetics and pharmacodynamics. Examples include polymorphisms in genes responsible for the activity of the enzymes dihydropyrimidine dehydrogenase (responsible for 5-fluorouracil metabolism), thiopurine *S*-methyltransferase (responsible for thiopurine metabolism), and uridine diphosphate-glucuronosyltransferase 1A1 (responsible for irinotecan metabolism).[90] Patients with deficiencies in these enzymes can experience significant, and possibly life-threatening, toxicity. Screening for these genetic variants might permit individualization of regimens to avoid toxicity and maximize antitumor effects. Monitoring of anticancer agents drug concentrations may also improve the therapeutic index. For example, pharmacokinetic and pharmacodynamic modeling is associated with improved responses and decreased toxicity in children with acute lymphoblastic leukemia.

The presence of other disease states (e.g., comorbidities) may also affect response to treatment by limiting treatment options. The overall functional status of a patient may be assessed using performance status scales, such as the Karnofsky and Eastern Cooperative Oncology Group scales (Table 135–10).[91] These scales can be used to predict patient tolerance of chemotherapy and to assess the effects of chemotherapy on the patient's level of activity and quality of life. For many cancers, performance status at diagnosis is the most important prognostic indicator.

Today's oncology clinician has a wealth of information to consider when designing a treatment approach for an individual patient. Patient-specific factors (e.g., performance status, comorbidities, renal and hepatic function, and pharmacogenomics), tumor-specific factors (e.g., pathology, stage, and molecular profile), and treatment goals (e.g., palliation and cure) are all considered when determining the best treatment option. Treatment cost can also be an important consideration.

COMBINATION CHEMOTHERAPY

Although single agents are sometimes employed, the more common approach to anticancer therapy involves administration of multiple agents to overcome factors for decreased patient response noted previously.[1,18,91] Initially, this approach was based on the Goldie-Coldman hypothesis, which addresses the issue of tumor cell heterogeneity and the inevitable development of drug resistance. Combination chemotherapy is given to target as many types of cells in the tumor as possible. Selection of agents for combination chemotherapy regimens involves consideration of drug-specific factors such as mechanism of action, antitumor activity, and toxicity profile. Drugs that possess minimally overlapping mechanisms of action and toxicities are combined, when possible. Myelosuppressive combinations are sometimes alternated with nonmyelosuppressive combinations to allow bone marrow recovery, while gaining additive antitumor effects. The selected agents should each have significant activity against the tumor that is to be treated. If a synergistic reaction is known to exist for two agents, they may be combined in various treatment regimens.

With the availability of new targeted therapies, one area of research is to determine the optimal ways to combine these agents, both with traditional anticancer agents and other targeted agents. In theory, these therapies make ideal combination agents because they target the underlying cancer biology while usually avoiding typical chemotherapy adverse effects. Clinicians must be careful in combining these agents based on clinical data that demonstrate additive or synergistic benefit. Combinations of chemotherapy and targeted agents have proven successful in breast and colon cancer. Predictive markers are needed to identify which patients may benefit from combinations of chemotherapy and targeted agents and how best to give them.

ADMINISTRATION OF CHEMOTHERAPY

DOSING AND ADMINISTRATION

Healthcare practitioners should monitor several clinical and laboratory values prior to the administration of chemotherapy. In general, a white blood cell (WBC) count ≥3,000 cells/mm^3 (3 × 10^9/L) or an absolute neutrophil count (ANC) ≥1,500 cells/mm^3 (≥1.5 × 10^9/L) and a platelet count of ≥100,000 cells/mm^3 (≥100 × 10^9/L) are usually required prior to administering chemotherapy. In addition, a chemistry panel is drawn to assess renal and hepatic function, especially for agents eliminated via those routes. Table 135–8 lists agents that require dosing adjustments and require specific laboratory tests prior to administration; failure to do so may result in overdosing and excessive toxicity from the agent.

Once it is determined that it is safe to administer, chemotherapy is generally dosed based on body surface area (BSA).[93] BSA is commonly used as an estimate of cardiac output and subsequent

distribution to the liver and kidneys, the primary determinants of drug elimination. The most common methods used to determine BSA are the Mosteller and DuBois formulas, which are listed in Table 135–9.

CLINICAL CONTROVERSY

The use of actual versus ideal body weight for calculating BSA is a source of debate in oncology. Although actual body weight is most often used, some clinicians prefer to use an adjusted body weight in obese patients. Clinicians need to clearly state the weight used in the BSA calculation. New methods of dosing using individual patient- and tumor-specific factors are an area of active research.

When determining the dose to be administered, healthcare practitioners should use with caution extreme values in BSA (values greater than 2 m^2) and assess patient clinical factors. New dosing methods are being developed to improve the accuracy of chemotherapy dosing and prevent both over- and underdosing. Carboplatin is now commonly dosed based on the patient's estimated glomerular filtration rate. This method, listed in Table 135–9, is known as the Calvert formula and has been demonstrated to achieve adequate levels of carboplatin without excessive toxicity.[94] Chemotherapy may also be dosed based on weight or drug levels and clinicians should be proficient in these calculations prior to dosing and administering any chemotherapy. Additional methods using pharmacogenomic testing are being studied to individualize chemotherapy doses.

SAFETY AND HANDLING ISSUES

The cytotoxic drugs used to treat cancer are carcinogenic, mutagenic, and teratogenic. Consequently, these drugs should be handled with care to avoid inadvertent exposure of healthcare professionals.[95] All pharmacies should have written procedures for handling these drugs safely, and all personnel should be oriented to these procedures. The United States Pharmacopeia (USP) chapter 797 regulates the preparation of extemporaneously compounded sterile preparations and should be used by centers that prepare chemotherapy.[95]

The most common avenue of exposure is via inhalation of aerosolized drug. Individuals preparing chemotherapy should work in a class II biologic safety cabinet and wear gowns and powder-free disposable latex gloves. The gowns should be made of lint-free, low-permeability fabric with a solid front, long sleeves, and tight-fitting elastic cuffs. Negative-pressure techniques should be employed in drug preparation to minimize aerosolization. Healthcare workers administering these agents should take similar precautions to avoid exposure. Kits for cleaning up chemotherapy spills should be located in all areas of the institution in which chemotherapy is handled. Cytotoxic waste should be disposed of properly, and patients should be informed of proper methods of disposing of potentially contaminated body excreta and cytotoxic waste.

GENERAL SUPPORTIVE CARE ISSUES

9 The treatment of cancer with most anticancer agents is complicated by the risk of multiple serious toxicities, many of which are life-threatening. Adverse events are commonly graded on a scale from no toxicity to death; a common scale used in clinical trials is the common toxicity criteria (CTC) for adverse events developed by the National Cancer Institute and the standard adverse event reporting classification system used in the United States for all drugs is the Medical Dictionary for Regulatory Activities (meddra). Specific toxicities, such as doxorubicin-induced cardiotoxicity and bleomycin-related pulmonary toxicity, were summarized earlier. Several adverse effects are common to many anticancer agents. These include nausea and vomiting, myelosuppression, mucositis, alopecia, infertility, and carcinogenesis. With the addition of targeted therapies, new toxicities such as rash have become issues for healthcare practitioners to address. Nutritional support and pain management are also important supportive care issues, although malnutrition and pain are not usually direct results of toxicity. The management of chemotherapy-induced nausea and vomiting and the basic principles of nutritional support and pain management are discussed in detail in other chapters.

Because many anticancer agents affect DNA synthesis, all rapidly proliferating cells are more sensitive to the toxic effects of chemotherapy. Normal tissues such as the bone marrow, intestinal mucosa, and hair follicles are such tissue sites where drug effects are manifested.

MYELOSUPPRESSION

10 Although not seen with all anticancer agents, myelosuppression is the most common dose-limiting side effect of cytotoxic agents. Myelosuppression is increased when chemotherapy is administered concurrently with radiation to the chest or pelvic region. Bone marrow suppression does not usually occur immediately after chemotherapy administration. Blood components that have already been produced must be consumed before the effect is evident. WBCs, especially neutrophil precursors, are most significantly affected because of their rapid proliferation and short life span (6 to 12 hours). Platelets (5- to 10-day life span) are also affected, but to a much less degree than neutrophils. Erythrocytes, with a 120-day life span, are affected the least. Usual nadirs, or lowest blood cell counts, occur at 10 to 14 days following chemotherapy administration, with recovery by 3 to 4 weeks. There are some exceptions to this general rule. The nitrosoureas, mitomycin C, and radiolabeled antibodies exhibit a delayed pattern of nadir (4 to 6 weeks) and recovery (6 to 8 weeks). Planned courses of chemotherapy may have to be delayed while waiting for the granulocyte count to return to normal. Patients with leukemia or receiving a stem cell transplant may have a more rapid nadir of about 5 to 7 days. A guide for suggested blood counts for a patient to safely receive myelosuppressive chemotherapy is listed in the previous section on chemotherapy administration.

Myelotoxicity is a desired therapeutic effect in patients with acute myeloid leukemia during induction chemotherapy. However, myelosuppression, particularly with fever, is an undesirable side effect during chemotherapy for other malignancies. If significant myelosuppression has occurred with prior courses of chemotherapy, the doses of the offending agent(s) in subsequent courses may be reduced. The magnitude of dose reduction is dictated by the degree of myelosuppression incurred and the incidence and severity of infection or bleeding. Empiric dosage reductions may be made for the first chemotherapy treatment if the patient has a low baseline WBC or platelet count, has diminished bone marrow reserve, has impaired drug-elimination, or is to receive a combination of several drugs that cause myelosuppression. Patients who have received multiple prior courses of other myelotoxic chemotherapy regimens or extensive radiation therapy, especially to the pelvis or chest, may have a decreased bone marrow reserve. They are more sensitive to the myelosuppressive effects of chemotherapy, and normal doses

may produce profound marrow toxicity. The pharmacokinetic profile of a myelosuppressive agent is also important in determining the appropriate dose. For example, the anthracyclines produce bone marrow suppression as an acute dose-limiting toxicity, and these agents depend on biliary excretion as their primary route of elimination. A patient with biliary obstruction may have compromised elimination of anthracyclines and is at increased risk for severe bone marrow suppression if the dose is not appropriately adjusted (Table 135–8).

However, in some tumors (e.g., breast cancer or lymphoma) dosage reduction may compromise antitumor response, leading to worse patient outcomes.[1] In patients who are responding well to treatment, some degree of myelosuppression is accepted by most healthcare practitioners if it is not compromising the patient's quality-of-life and the tumor is responding to therapy. In these patients, empiric use of hematopoietic growth factors provides an alternative to dose reduction.

Anemia

⑩ Although usually not life-threatening, anemia is the most common hematologic complication of cancer chemotherapy.[96] The incidence of anemia depends on several factors, including the type and duration of therapy and the type and stage of the underlying malignancy. For example, carboplatin is more commonly associated with anemia than many other chemotherapeutic agents. Multiple conditions are known to cause anemia in cancer patients, including chronic gastrointestinal blood loss, nutrient deficiency (e.g., iron and folate), chemotherapy and radiation therapy, bone marrow invasion by the tumor, hemolysis, renal dysfunction, and anemia of chronic disease. Of all the signs and symptoms of anemia, fatigue is most common in cancer patients.[96] In fact, fatigue is the most commonly reported symptom overall in patients undergoing chemotherapy. The presence of fatigue is correlated with the severity of anemia; treatment of anemia may result in improvement in fatigue and quality-of-life. Anemia is only one of many possible causes of fatigue in patients with cancer. Other common causes of fatigue include insomnia, depression, unrelieved pain, and the underlying malignancy.

Previously, the only option for the treatment of chemotherapy-related anemia was red blood cell transfusions. This intervention is still the mainstay of acute management, but the availability of the recombinant human erythropoietic products—epoetin alfa and darbepoetin alfa—has provided another therapeutic option.[96] Several studies have documented the efficacy of these agents in the anemia associated with chemotherapy. Both epoetin alfa and darbepoetin alfa increase hemoglobin and hematocrit and decrease transfusion requirements. Improvements in other outcomes such as fatigue and quality-of-life are under further investigation. One difference between the products is that darbepoetin has a threefold longer half-life, which allows for less-frequent administration of darbepoetin in the clinical setting.[97]

Clinical practice guidelines to guide the appropriate use of erythropoietic agents have been developed.[96] The first step is to evaluate the underlying cause of the anemia and initiate specific therapy as indicated. For example, patients with iron-deficiency anemia should receive iron supplementation. Patients with chronic bleeding or hemolysis should not receive erythropoietic therapy, as this does not target the underlying cause of their anemia. Epoetin alfa and darbepoetin alfa may be considered for chemotherapy- or cancer-related anemia only after otherwise treated causes of anemia have been ruled out. The 2010 National Comprehensive Cancer Network guidelines suggest starting symptomatic patients when their hemoglobin is less than 10 g/dL (100 g/L; 6.21 mmol/L) with a target hemoglobin of 10 to 12 g/dL (100 to 120 g/L; 6.21 to 7.45 mmol/L) to achieve maximum benefit.[96] Several early indicators of response have been proposed, including an increase in hemoglobin of 1 g/dL (10 g/L; 0.62 mmol/L) above baseline, a decline in ferritin, or an increase in the absolute reticulocyte count after 2 to 4 weeks of therapy. These surrogate endpoints can be used to identify nonresponders early, so that therapy may be modified or discontinued, as indicated. Serum erythropoietin levels have minimal utility in predicting response or monitoring therapy and are often not measured in clinical practice.

Patients should only receive the labeled doses of the drugs, which are epoetin alfa 40,000 units once, each week or darbepoetin alfa at a dose of 2.25 mcg every other week or 500 mcg every 3 weeks. After 4 to 6 weeks, the hemoglobin should be reassessed. In patients who do not achieve at least a 1 g/dL (10 g/L; 0.62 mmol/L) rise in hemoglobin, the 2010 National Comprehensive Cancer Network guidelines recommend to increase the epoetin alfa dose to 60,000 units once a week and the darbepoetin alfa dose to 4.5 mcg every other week.[96] Iron stores should be checked to rule out iron deficiency as a cause of treatment failure. Supplemental intravenous iron may be administered to increase the response to erythropoietic therapy. Treatment should be discontinued in patients who do not respond after 8 weeks at the higher dose.

Several serious outcomes have been reported with the use of these agents that have resulted in significant changes to their approved labeling and have drastically decreased their use.[96] Recent studies in advanced breast, cervical, head and neck, lymphoma, and non-small-cell lung cancers reported decreased survival in cancer patients receiving erythropoietic drugs for correction of anemia resulting in a black box warning in the package insert. This warning restricts the use of these agents to patients receiving myelosuppressive chemotherapy without curative intent and requires that the minimal dose to reduce blood transfusions be used. Most of these studies had target hemoglobin levels of >12 g/dL (>120 g/L; >7.45 mmol/L), therefore use of these agents in patients with hemoglobin levels >12 g/dL (>120 g/L; >7.45 mmol/L) should be avoided. Agents should be stopped when the chemotherapy-related anemia resolves and these agents should not be used on patients with cancer-related anemia. Patients are also required to be given a medication guide that warns them of this risk without conclusive benefits outside of decreased blood transfusions.

Other serious adverse effects related to erythropoietic products include thrombosis and pure red cell aplasia, which may result in an increased mortality from use. These events have generally occurred when the target hemoglobin of 12 g/dL (120 g/L; 7.45 mmol/L) is exceeded or the hemoglobin rises too quickly. The 2010 National Comprehensive Cancer Network guidelines recommend that if hemoglobin increases by more than 1 g/dL (10 g/L; 0.62 mmol/L) in a 2-week period, the dose of either product should be reduced by 25% or by the amount needed to avoid blood transfusions. If hemoglobin levels exceed 12 g/dL (120 g/L; 7.45 mmol/L) while on therapy, healthcare practitioners should hold therapy and reinitiate therapy at dose to avoid transfusions if the patient's hemoglobin falls below 10 g/dL (100 g/L; 6.21 mmol/L).[96]

Other rare and generally mild adverse effects include pain at injection site, rash, flu-like symptoms, seizures, and hypertension.

Neutropenia

⑩ When the ANC falls below 500 cells/mm^3 (0.5 × 10^9/L), infection risk increases.[98] The ANC may be calculated by multiplying the percentage of neutrophils (segmented plus banded neutrophils) by the total WBC count. The risk of infection is also directly proportional to the duration of neutropenia. Other risk factors for infection include alteration in the integrity of physical defense barriers and the functional integrity of WBCs. The patient's underlying cancer

and treatment with cytotoxic drugs and radiation can affect neutrophil function. The diagnosis of infection in the neutropenic patient is complicated by the lack of WBCs. Usual signs and symptoms of infection, such as pus, abscesses, and infiltrates on chest radiography, are often absent as a result of the lack of WBCs. Clinicians must rely on fever as an indication of infection in these patients. Definitive culture results may take days, and a septic neutropenic cancer patient can die within hours if not treated. Therefore, the basic approach to the management of the febrile neutropenic cancer patient is prompt initiation of empiric antibiotics. The antibiotics are chosen based on reliable coverage of the most likely organisms, antibiotic sensitivities at the institution, the patient's signs and symptoms (if present), side-effect profiles, and cost.[98] The most common source of infection in these patients is self-infection with body flora, which includes both gram-positive and gram-negative bacteria. Specific treatment of infections in immunocompromised hosts is discussed in Chapter 131.

Numerous methods have been explored to prevent infections in cancer patients. Colony-stimulating factors (CSFs) are commonly employed for this purpose.[98] These hormones are naturally occurring proteins that are essential for the normal growth and maturation of blood cell components (Fig. 135–11). The CSFs have the ability to enhance the production and also the function of their target cells. Two agents, G-CSF (granulocyte colony-stimulating factor) and GM-CSF (granulocyte-macrophage colony-stimulating factor) are commercially available in the United States. G-CSF (filgrastim) specifically stimulates the production of neutrophilic granulocytes. GMCSF (sargramostim) promotes the proliferation of granulocytes (neutrophils and eosinophils) and monocytes/macrophages.[99] Although GM-CSF stimulates megakaryocytes, no consistent effect on platelet production has been observed in clinical trials. Both agents initially enhance demargination and mobilization of mature cells from the marrow and then provide constant stimulation of stem cell progenitors. CSFs are produced by recombinant DNA technology, and several host cells are used to produce CSFs, including bacteria (*E coli*), yeast, and mammalian cells (Chinese hamster ovary cells). Products derived from yeast or mammalian sources are glycosylated to varying degrees, as are naturally occurring CSFs, while those derived from *E coli* are nonglycosylated.[99] This difference does not result in any clinically

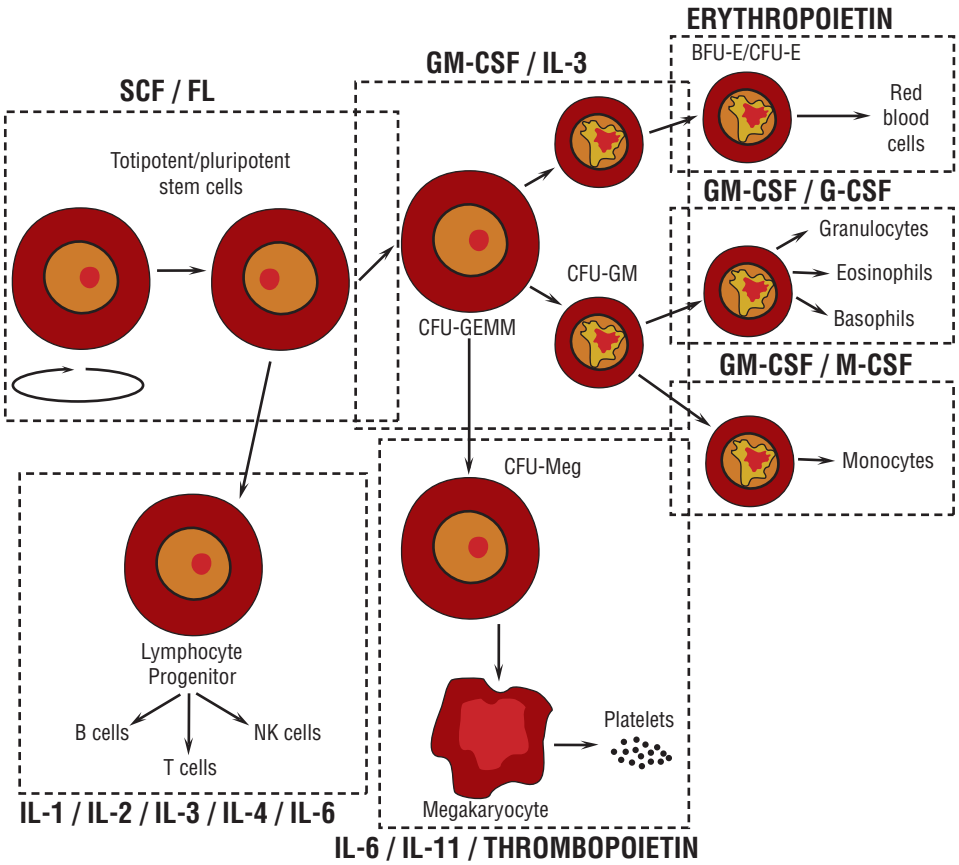

FIGURE 135-11. Sites of action of hematopoietic growth factors in the differentiation and maturation of marrow cell lines. A self-sustaining pool of marrow stem cells differentiates under the influence of specific hematopoietic growth factors to form a variety of hematopoietic and lymphopoietic cells. Stem cell factor (SCF), FTL- 3 ligand (FL), interleukin-3 (IL- 3), and granulocyte/macrophage colony-stimulating factor (GM-CSF), together with cell–cell interactions in the marrow, stimulate stem cells to form a series of burst-forming units (BFU) and colony-forming units (CFU): CFU-GEMM, CFU-GM, CFU-Meg, BFU-E, and CFU-E (GEMM, granulocyte, erythrocyte, monocyte, and megakaryocytes; GM, granulocyte and macrophage; Meg, megakaryocyte; E, erythrocyte). After considerable proliferation, further differentiation is stimulated by synergistic interactions with growth factors for each of the major cell lines—granulocyte colony-stimulating factor (G-CSF), monocyte/macrophage-stimulating factor (M-CSF), thrombopoietin, and erythropoietin. Each of these factors also influences the proliferation, maturation, and, in some cases, the function of the derivative cell line. *(Adapted from Kaushansky K and Kipps TJ. Hematopoietic agents: Growth factors, minerals and vitamins. In: Brunton LL, Lazo JS, Parker KL, eds. Goodman & Gilman's The Pharmacologic Basis of Therapeutics, 11th ed. New York: McGraw-Hill, 2006: 1435.)*

significant effects on neutrophil production. Pegfilgrastim is a long-acting CSF, created by addition of a polyethylene glycol molecule to G-CSF.[100] Clinical trials have demonstrated that a single dose of pegfilgrastim provides equivalent effects to 10 to 11 days of daily G-CSF, with similar side-effect profiles.

The CSFs reduce the incidence, magnitude, and duration of neutropenia when used as preventive therapy following a variety of myelosuppressive chemotherapy regimens.[98,101] These effects have been accompanied by a modest decrease in febrile days, infections, and days on antibiotics. In some studies, use of CSFs also resulted in a decrease in the incidence of mucositis. Growth factors have also permitted the administration of subsequent chemotherapy courses on schedule, resulting in enhanced dose intensity. However, the increased dose intensity provided by the CSFs has not consistently translated into improved tumor response or survival. Because of lack of impact on response rates and survival, decisions regarding appropriate use of growth factors should be based on weighing proven clinical benefits against economic considerations. The American Society of Clinical Oncology has developed evidence-based clinical practice guidelines to promote appropriate use of the CSFs.[101]

Growth factors may be used in either primary or secondary prophylaxis of neutropenia. Primary prophylaxis refers to the use of CSFs to prevent neutropenia with the first cycle of chemotherapy. Recently, the American Society of Clinical Oncology stated that this strategy is clinically and economically appropriate for patients who are receiving a chemotherapy regimen with a 20% or higher risk of febrile neutropenia.[108] Secondary prophylaxis refers to the use of growth factors to prevent recurrent neutropenia in patients who had experienced neutropenia with the prior cycle of chemotherapy. It is recommended that secondary prophylaxis be reserved for patients with chemosensitive cancers where dose reduction may affect disease-free or overall survival.[101]

Pegfilgrastim, G-CSF, and GM-CSF are used clinically to prevent febrile neutropenia after administration of standard doses of chemotherapy although only pegfilgrastim and G-CSF are approved for this indication. One exception is in acute myelogenous leukemia, in which both G-CSF and GM-CSF have been demonstrated to reduce the duration of neutropenia, often accompanied by modest decreases in hospitalization and infectious complications, after induction chemotherapy. Benefits have been most clearly documented in patients older than age 55 years. Similar data are available for G-CSF in the treatment of patients with acute lymphoblastic leukemia. These beneficial effects, however, have not resulted in improved response rates or overall survival.[101]

The role of CSFs in the treatment of established neutropenia is less-well defined. Most studies suggest no or only minimal clinical benefit from use of CSFs in treating neutropenia; therefore, CSFs should not be routinely employed in patients with established neutropenia, regardless of the presence of fever. However, certain high-risk patients with fever and neutropenia may benefit from CSFs: neutropenia >10 days, ANC <100 cells/mm^3 (>0.1 × 10^9/L), age <65 years, infectious complications (pneumonia, sepsis, or invasive fungal infections), and patients who are hospitalized at the time of the development of neutropenic fever.[98,101]

Both G-CSF and GM-CSF have also proven effective in acceleration of hematopoietic engraftment and in treatment of graft failure following hematopoietic stem cell transplantation. Other uses for the CSFs include peripheral blood stem cell mobilization, neutropenia in patients with acquired immune deficiency syndrome, myelodysplastic syndromes, congenital neutropenia, and aplastic anemia. Growth factors should not be used in patients receiving concomitant chemotherapy and radiotherapy, especially if the radiation involves the mediastinum. These patients appear to experience more significant thrombocytopenia when administered CSFs.

At currently recommended doses, the CSFs are well tolerated. Side effects are more commonly seen with GM-CSF and may be related to the drug's ability to enhance binding of neutrophils to endothelial cells or to activation of monocytes/macrophages, which may stimulate the release of cytokines such as IL-1 and tumor necrosis factor.[99] The most common toxicity of the CSFs is bone pain (20% to 25% of patients), which can be treated with acetaminophen. Other side effects of G-CSF include an increase in lactate dehydrogenase, alkaline phosphatase, and uric acid levels. Additional toxicities of GM-CSF include constitutional symptoms, such as low-grade fever, myalgia, arthralgia, lethargy, and mild headache. GM-CSF may also produce an elevation in liver transaminases. At higher doses of GM-CSF, pleural and pericardial effusions, capillary-leak syndrome, and thrombus formation may occur. A first-dose reaction described after GM-CSF administration has been reported more commonly with the *E coli*-derived product (molgramostim), which is not commercially available in the United States. This reaction is more common after intravenous infusion and consists of dyspnea, facial flushing, hypotension, hypoxia, and tachycardia. Both G-CSF and GM-CSF may produce mild erythema at subcutaneous injection sites, as well as a generalized maculopapular rash with either subcutaneous or intravenous administration. Pegfilgrastim adverse effects are similar to G-CSF and are treated the same.[100]

The dosing and administration of CSFs approved for prophylaxis of chemotherapy-induced neutropenia after standard dose chemotherapy is as follows: G-CSF 5 mcg/kg until the ANC reaches 10,000 cells/mm^3 (10 × 10^9/L) (or clinically safe) or pegfilgrastim 6 mg as a single dose. Both agents should be started between 24 and 72 hours after chemotherapy; G-CSF can be stopped the day before chemotherapy whereas pegfilgrastim needs to be stopped within 14 days of the next dose because of its long half-life. The dose for other uses varies, for instance in the setting of peripheral blood stem cell mobilization doses of 10 mcg/kg per day are usually used. The recommended dose of GM-CSF is 250 mcg/m^2 per day. Pharmacokinetic data favor subcutaneous injection as the most effective route. However, in patients in whom subcutaneous injections are not feasible (e.g., anasarca), G-CSF and GM-CSF may be given intravenously. Pegfilgrastim should not be given intravenously. Because of the high cost associated with CSF use, alternative dosing regimens have been explored. These regimens attempt to decrease the total amount of CSF used by either delaying the start of CSFs (e.g., to day 3 after chemotherapy), decreasing the dose (e.g., to 3 mcg/kg/day of G-CSF), or decreasing the duration of CSF therapy. Standardized doses of 300 mcg or 480 mcg of G-CSF and 500 mcg of GM-CSF, based on product vial sizes, are often used to minimize waste. Specifically, the posttreatment target ANC of 10,000 cells/mm^3 (10 × 10^9/L) recommended by product information is often reduced in clinical practice to 5,000 cells/mm^3 (5 × 10^9/L) or lower. For patients receiving pegfilgrastim, it is important that additional CSFs not be administered for the 10 days following administration, as additional benefit is not realized.[100]

Thrombocytopenia

Chemotherapy-induced thrombocytopenia puts the patient at risk for significant bleeding. To date, platelet transfusions remain the mainstay of management. At most centers, platelet transfusions are reserved for patients with a platelet count of <10,000 cells/mm^3 (<10 × 10^9/L) unless they are actively bleeding, must undergo a surgical procedure, or have documented infections or fever in which the threshold is higher. For patients with nonmyeloid malignancies who experienced significant thrombocytopenia with a prior cycle of chemotherapy, oprelvekin (IL-11) may be considered as secondary prophylaxis.[102] When used after chemotherapy regimens asso-

ciated with a high risk of thrombocytopenia, oprelvekin decreased the need for platelet transfusions, as well as the numbers of platelets required for transfusion. Unfortunately, oprelvekin is associated with some significant adverse effects, mostly related to fluid retention (e.g., edema, dilutional anemia, dyspnea, and pleural effusions). Cardiac toxicity, especially tachycardia, and atrial fibrillation and flutter also have been observed. Prophylactic oprelvekin also is significantly more expensive than platelet transfusions.[103] Considering the modest clinical benefit, the adverse effects, and the high cost, oprelvekin use should be reserved for patients who are at high risk for severe thrombocytopenia from chemotherapy where dose reduction is known to compromise disease response. Other CSFs, such as IL-1, −3, and −6, have also been studied, but significant impact on platelet counts with an acceptable adverse effect profile has not been demonstrated.[85,102] The discovery and development of thrombopoietin, a megakaryocyte-stimulating factor, may represent the most significant factor in the future of thrombocytopenia treatment.

MUCOSITIS

The gastrointestinal mucosa is composed of epithelial cells with a high mitotic index and rapid turnover rate, making it a common site of chemotherapy-induced toxicity.[104] The subsequent inflammation, or mucositis, can lead to painful ulcerations, local infection, and inability to eat, drink, or swallow. Disruption of the gastrointestinal mucosal barrier may also provide an avenue for systemic microbial invasion. The time course for development and resolution of mucositis often parallels that of neutropenia. Agents most commonly associated with mucositis include 5-FU, doxorubicin, and methotrexate. Currently, the most effective means of preventing mucositis is through good oral hygiene. Patients who are at high risk for this toxicity (those with poor dentition, high-dose chemotherapy, or radiation therapy involving the oropharynx) should be evaluated by a dentist prior to chemotherapy and should be instructed to rinse their mouths frequently with baking soda and salt water or plain saline rinses during and between courses of chemotherapy. Clinical practice guidelines for the prevention and treatment of cancer therapy-induced mucositis were recently published.[104] The benefit of chlorhexidine rinses over saline rinses is unclear. In patients undergoing radiation therapy to the head and neck region, chlorhexidine rinses have detrimental effects on the oral mucosa. For patients receiving 5-FU treatment, the use of ice (oral cryotherapy) may decrease the risk for mucositis by decreasing drug delivery to the oral mucosa. A better understanding of the pathophysiology of mucositis has resulted in identification of promising new agents to better prevent mucositis. The keratinocyte growth factor palifermin is approved for use in patients receiving high-dose chemoradiotherapy prior to hematopoietic stem cell transplantation. Palifermin is given intravenously at a dose of 60 mcg/kg/day for 3 consecutive days immediately before the initiation of conditioning therapy and then again for 3 days after hematopoietic stem cell transplantation.[105] The effect of palifermin on solid tumor growth is unknown and its use in nonhematologic cancers is not recommended.

After mucositis has developed, treatment is mainly supportive, including use of topical or systemic analgesics and oral hygiene (including the rinses described).[104] Viscous lidocaine, diphenhydramine liquid, and dyclonine are topical anesthetics commonly employed. Severe cases of mucositis may lead to dehydration and require intravenous hydration and pain medications including patient-controlled analgesia pumps. Local infections caused by *Candida* species and reactivation of herpes simplex viruses are common in these patients. Suspicious lesions should be cultured, and appropriate antifungal and/or antiviral treatment should then be instituted. Antifungal therapy may be delivered topically for mild infections (thrush) with clotrimazole troches or nystatin oral suspension. For more severe oral or esophageal fungal infections, systemic treatment with oral fluconazole or intravenous antifungals is indicated.

Mucosal damage can occur at any point along the entire length of the gastrointestinal tract. In the lower portion of the gastrointestinal tract, this damage is usually manifested as diarrhea (mild to life-threatening in nature) and abdominal pain. Support with intravenous fluids and electrolyte supplementation should be initiated promptly in severe cases. After infectious causes have been ruled out, diarrhea can safely be treated with antispasmodics such as Lomotil or loperamide. The somatostatin analog octreotide has also been used successfully to treat severe cases of chemotherapy-induced diarrhea; guidelines exist to assist practitioners in treating this toxicity.[104,106]

CUTANEOUS REACTIONS

Cutaneous reactions to chemotherapy are generally reversible and self-limiting upon chemotherapy dose reductions or delays. Common reactions include localized rash, photosensitivity, skin hyperpigmentation, nail changes, and hand–foot syndrome, but can be associated with severe hypersensitivity reactions. Common agents known to cause rash in patients include cytarabine, 5-FU, and bleomycin.

In targeted therapies, particularly those that target the EGFR receptor, rash is often the most common adverse effect associated with therapy and requires prompt recognition by healthcare professionals to prevent drug discontinuation. Some studies suggest that the rash may be a surrogate marker of response to these agents, perhaps indicating a genetic predisposition to response with EGFR targeted agents. Rash occurs in up to two thirds of patients on EGFR inhibitors, most commonly in the first month on treatment with the typical site of presentation being the face and upper torso. Although no clear guidelines exist for the treatment of this rash, patients should be supported based on their presentation.[64] Anecdotal reports indicate that emollients help if patients complain of dry skin, topical and systemic antibiotics may help if the rash becomes infected, and steroids may help prevent itching and inflammation.[64]

ALOPECIA

Although not a life-threatening side effect of chemotherapy, the toxicity that many patients find most distressing is alopecia. Alopecia from chemotherapy is usually temporary, and the degree of hair loss varies widely.[107] Loss of hair is not limited to the scalp; any area of the body may be affected. Patients receiving a taxane as part of their chemotherapy regimen are especially prone to total body alopecia. Hair loss usually begins 1 to 2 weeks after chemotherapy, and regrowth may begin before the chemotherapy courses are completed. Cryotherapy (local application of ice) and scalp tourniquets have both been investigated as methods of preventing alopecia. Both techniques produce vasoconstriction, resulting in decreased exposure of hair follicles to the chemotherapy agents. These techniques are not uniformly effective and are contraindicated in patients with cancers that may metastasize to the scalp, such as leukemia and lymphoma.

EXTRAVASATION

Vesicants are agents that may cause severe tissue damage if they escape from the vasculature.[108] These agents include the anthracyclines, actinomycin D, the vinca alkaloids, mitomycin C, nitrogen mustard, and the taxanes. The anthracyclines are the most noto-

rious agents, and the most extensively investigated. The tissue damage may result in prolonged pain, tissue sloughing, infection, and loss of mobility. Prompt initiation of the appropriate interventions is important to minimize morbidity. Unfortunately, most information on extravasation management is anecdotal; few controlled clinical trials have been conducted to determine optimal intervention strategies. Consequently, prevention is the focus of extravasation management. The most important method of prevention is good administration technique, but extravasations may occur despite good administration technique.[108] The vein selected for administration should be on the distal portion of the arm. The large veins of the forearm are desirable because if a drug does extravasate, there is adequate soft-tissue coverage to protect crucial structures like nerves and tendons, and joint function is not put at risk. Peripherally administered vesicants should be given slowly via intravenous injection (IV push) through the side arm of a running intravenous line. The person administering the vesicant should verify needle stability and adequate blood return after each 1 to 2 mL of drug is injected. Vesicants should not be administered by intravenous infusion unless the patient has a central venous catheter. For extravasation of vesicants, one of the most important interventions is the application of ice packs to the affected area. One exception to this rule is the vinca alkaloids, which are better managed with application of heat. Only a few antidotes to vesicant agents are employed clinically. Sodium thiosulfate is used to neutralize nitrogen mustard extravasations, and hyaluronidase (if available) can improve the outcome after extravasation of vinca alkaloids, etoposide, and taxanes. Topical application of dimethyl sulfoxide may be an effective method for managing anthracycline and mitomycin C extravasations.[108] A new packaging of dexrazoxane, marketed as Totect®, has been approved to treat anthracycline extravasation and is given as an intravenous infusion.[109]

INFERTILITY

Advances in the treatment of some cancers, such as Hodgkin disease and testicular cancer, have produced long-term survivors and the opportunity to examine the late consequences of chemotherapy administration. Infertility and secondary cancers have emerged as important late effects. The gonadal toxicities of chemotherapy have not received much attention in the past because they are not life-threatening. High rates of fertility deficits and sexual dysfunction have been noted for both men and women.[110] In men, antitumor drugs produce severe oligospermia or azoospermia as well as infertility. Serum testosterone levels are only rarely altered. The recovery of spermatogenesis after completion of chemotherapy is unpredictable. Men receiving combination chemotherapy appear to sustain more long-lasting adverse effects on fertility than do men receiving single-agent therapy. Age, total dose, duration of therapy, and type of drug are other important variables. In women, toxic effects on the ovaries result clinically in amenorrhea, vaginal epithelial atrophy, and menopausal symptoms. These effects are related to dose and age. Younger patients are more resistant to the effects on the ovaries. As with men, the recovery of fertility is unpredictable, but women younger than 25 years of age appear to have the best outcomes. The effects of the alkylating agents on fertility have been extensively studied. This group of drugs exerts profound and consistently detrimental effects on reproductive function.[110] The impact of this drug-induced amenorrhea on patient survival has been less clear with some trials demonstrating a benefit to those patients who achieve chemotherapy-induced amenorrhea. Trial results have been mixed though and conclusive statements cannot be made at this time. Less is known about commonly used agents such as doxorubicin, taxanes, and platinum compounds. The risk of infertility should be discussed with all patients prior to receiving chemotherapy and they should be informed about options for fertility preservation.

SECONDARY MALIGNANCIES

Secondary cancers induced by chemotherapy and radiation are a serious long-term complication.[111] Although many types of solid tumors have been reported as chemotherapy-induced malignancies, acut myelogenous leukemia or myelodysplastic syndromes are the most common secondary cancers. Acute myelogenous leukemia or myelodysplastic syndrome has been reported following successful treatment of Hodgkin and non-Hodgkin lymphoma, acute leukemias, multiple myeloma, breast cancer, and advanced ovarian cancer. For curable cancers, the relatively small risk for occurrence of secondary malignancies is far outweighed by the benefits of survival in large numbers of patients. However, for cancers such as ovarian cancer, the risk of leukemia is not offset by improved survival in patients treated with chemotherapy. The issue of secondary malignancies is of particular concern in patients receiving adjuvant chemotherapy. As with the late complication of infertility, the anticancer agents primarily associated with secondary cancers are the alkylating agents. Etoposide, teniposide, radionucleotides, and the anthracyclines also are linked to secondary leukemias. Solid tumors as secondary malignancies occur more commonly after treatment with radiation than with chemotherapy.

ABBREVIATIONS

ADCC: antibody dependent cellular cytotoxicity
ANC: absolute neutrophil count
ara-C: cytarabine
ara-CTP: active triphosphate form of cytarabine
BCNU: carmustine
BSA: body surface area
CCNU: lomustine
CDC: complement-dependent cytotoxicity
CR: complete response
CSF: colony-stimulating factor
DHFR: dihydrofolate reductase
DNA: deoxyribonucleic acid
DNMT: DNA methyltransferase
EGFR: epidermal growth factor receptor
5-FU: fluorouracil
G_0: dormant phase of the cell cycle
G_1: first gap phase of the cell cycle
G_2: second gap or premitotic phase of the cell cycle
G-CSF: granulocyte colony-stimulating factor
GM-CSF: granulocyte-macrophage colony-stimulating factor
HAMA: human antimouse antibodies
HER: human epidermal growth factor receptor
HDAC: histone deacetylases
IL: interleukin
IFN: interferon
6-MP: 6-mercaptopurine
M: mitosis
MoAB: monoclonal antibody

mRNA: messenger RNA
MTIC: monomethyl triazeno imidazole carboxamide
mTOR : mammalian target of rapamycin
MTX: methotrexate
NF-κB: nuclear factor-κB
Pgp: p-glycoprotein
RAR: retinoic acid receptor
RNA: ribonucleic acid
rRNA: ribosomal RNA
RXR: retinoid X receptor
S: DNA synthesis phase of the cell cycle
tRNA: transfer RNA
VEGF: vascular endothelial growth factor
WBC: white blood cell

CHAPTER 136

Breast Cancer

LAURA BOEHNKE MICHAUD, CHAD M. BARNETT, AND FRANCISCO J. ESTEVA

KEY CONCEPTS

1. Breast cancer is usually diagnosed in early stages, when it is a highly curable malignancy.
2. Local therapy of early-stage breast cancer consists of modified radical mastectomy or lumpectomy plus external beam radiation therapy. The surgical approach to the ipsilateral axilla may consist of a full level I/II axillary lymph node dissection or a lymph node mapping procedure with sentinel lymph node biopsy.
3. Adjuvant endocrine therapy reduces the rates of relapse and death in patients with hormone receptor-positive early breast cancer tumors. Adjuvant chemotherapy reduces the rates of relapse and death in all patients with early stage breast cancer.
4. The choice of chemotherapy regimen, dose, schedule and duration of therapy, and the choice of endocrine therapy are controversial and rapidly changing as results from ongoing randomized clinical trials are reported.
5. Neoadjuvant chemotherapy is appropriate for patients with locally advanced breast cancer, inflammatory breast cancer, and selected patients with early breast cancer followed by local therapy and further adjuvant systemic therapy.
6. Initial therapy of metastatic breast cancer in most women with hormone receptor-positive tumors should consist of hormonal therapy.
7. Women with metastatic breast cancer who have hormone receptor-positive tumors and respond to an initial hormonal manipulation will usually respond to a second hormonal manipulation.
8. Approximately 60% of women with metastatic breast cancer will respond to chemotherapy regimens; anthracycline- and taxane-containing regimens are the most active.
9. The goal of adjuvant chemotherapy is curative, whereas the goal of chemotherapy in the metastatic setting is palliative.
10. Although controversial, annual screening mammography in women younger than 50 years of age is clearly beneficial and many national and international studies demonstrate a reduction in breast cancer mortality from annual or biennial screening mammography in women ages 50 to 70 years.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

Breast cancer is the most common site of cancer and is second only to lung cancer as a cause of cancer death in American women. It is estimated that 207,090 new cases of breast cancer will be diagnosed and that 39,840 women will die of breast cancer in 2010.[1] In addition to invasive breast cancers, it is estimated that 54,010 cases of noninvasive, or in situ, cancer will be diagnosed among women in the United States in 2010.

Female breast cancer incidence rates vary considerably across racial and ethnic groups. The average annual age-adjusted incidence rate from 2001 to 2005 was 130.6 cases per 100,000 among white females, 117.5 cases among African Americans, 90.1 cases in Hispanics, 89.6 cases among Asian-Americans/Pacific Islanders, and 75.0 cases in American Indians/Alaska Natives.[2] Reasons for the higher incidence rates in whites than in other racial and ethnic groups may include differences in reproductive and lifestyle factors, and access to and use of screening.[3]

Female breast cancer incidence rates have increased for all women combined since 1980, although the rate of increase slowed in the 1990s, and has decreased by approximately 2% per year from 1999 to 2006. Factors that may explain the decrease in incidence include a slight reduction in the use of screening mammography and decreased use of postmenopausal hormone-replacement therapy (HRT).[2] The incidence of ductal carcinoma in situ (DCIS) also increased rapidly between the early and late 1980s, and continues to increase. The increase in DCIS is largely attributed to increased use of screening mammography, because most cases of DCIS manifest solely as clustered microcalcifications seen on mammography.[3]

1 For all racial and ethnic groups, most breast cancers are diagnosed at an early stage, when tumors are small and localized. However, a higher proportion of disease is diagnosed at more advanced stages in African American and other minority women than in white women. The death rate is also higher among African American women than white women despite the lower incidence. From 2001 to 2005, the breast cancer death rate was highest in African Americans (33.5 cases per 100,000 women), followed by whites (24.4), American Indians/Alaska Natives (17.1), Hispanics (15.8), and Asian-Americans/Pacific Islanders (12.6).[2] The cause of this disparity between white and African American women is controversial, with possible explanations including access to care, socioeconomic status, cultural differences, higher stage at diagnosis, and more aggressive biologic features. Despite these differences, overall mortality rates from breast cancer in the United States have declined since 1990. These declines have been attributed to increased use of screening and effectiveness of adjuvant treatment.[4,5] Figure 136–1 shows the temporal trends in incidence and mortality by race.

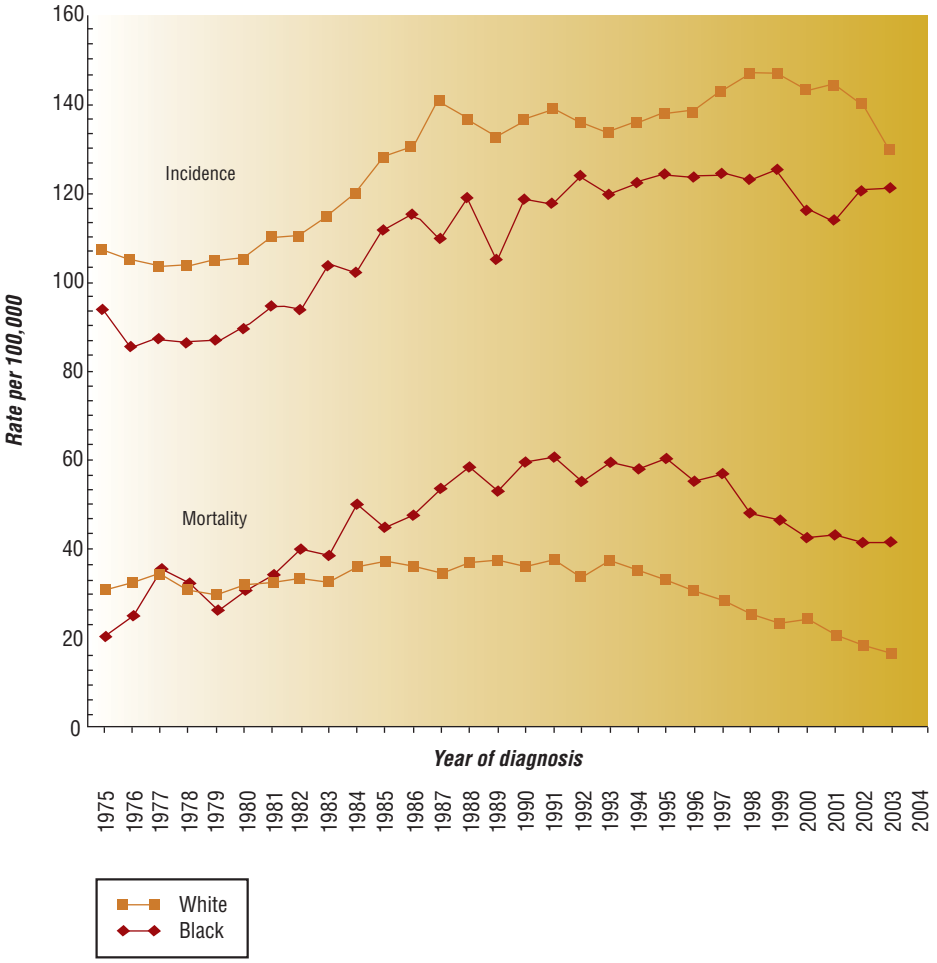

FIGURE 136-1. Breast cancer incidence and mortality rates by race, 1975–2004. *(From reference 2.)*

The median age at diagnosis for breast cancer is between the ages of 60 and 65 years.[2] Although lung cancer is the leading cause of cancer deaths for women regardless of age, breast cancer is the leading cause of cancer deaths for females between the ages of 20 and 59 years.[1]

EPIDEMIOLOGY AND ETIOLOGY

The two variables most strongly associated with the occurrence of breast cancer are gender and age. Although one commonly thinks of breast cancer as a disease confined to women, about 1,970 cases of male breast cancer will be diagnosed in the United States in 2010.[1] Male gender had been considered a poor prognostic factor in some investigations, but it is now believed that higher mortality rates in men are attributable to more advanced disease at the time of diagnosis. When stage and other known prognostic factors are controlled for, the clinical outcome for men with breast cancer is comparable to women.[6] Likewise, treatment of male breast cancer is similar to treatment of breast cancer in females.

The incidence of breast cancer increases with advancing age. A frequently quoted breast cancer statistic is that 1 in 8 women will develop breast cancer during their lifetime. It should be emphasized that this is a cumulative lifetime risk of developing the disease from birth to death. The 1-in-8-women figure is often misinterpreted by women who assume that it translates into 1 in 8 women being diagnosed with breast cancer each year. A more useful method of presenting the risk data is based on age intervals.[7] Table 136–1 shows that the risk of a woman developing breast cancer before the age of 40 years is about 1 in 206, and more than half the risk occurs after age 60 years.

An understanding of the relationship between age and the incidence of breast cancer is particularly relevant when one discusses "risk factors" or factors other than age that increase a woman's probability of developing breast cancer. The relative risk (RR) of developing breast cancer for an individual woman in a defined risk group is usually multiplied by the probability of a woman developing breast cancer during her lifetime, and this figure is taken as the cumulative lifetime risk of that individual developing breast cancer. However, the risk of developing breast cancer depends on age. Therefore, a more meaningful way to counsel patients regarding their risk of developing breast cancer based on the presence of a known risk factor incorporates an age-specific incidence rate, not cumulative lifetime risk. For example, if a 40-year-old woman with a strong family history of breast cancer has a RR ratio of 2.0, her risk of developing breast cancer by the age of 50 is only 7.6% (2 × 3.8) not 24% (2 × 12) (Table 136–1). It is also important to note that recognized risk factors are not additive in a simple mathematical sense.

TABLE 136-1 Risk of Developing Breast Cancer, Women, All Races 2004–2006

Age Interval (years)	Probability (%) of Developing Invasive Breast Cancer during the Interval
Birth–39	0.49 or 1 in 206
40–59	3.75 or 1 in 27
60–69	3.40 or 1 in 29
70 and older	6.50 or 1 in 15
From birth to death	12.08 or 1 in 8

SEER, Surveillance Epidemiology and End Results.
(From reference 1.)

Finally, it should be emphasized that most women with breast cancer have no identifiable major risk factor, indicating that the search for the etiology of this disease is largely incomplete.

A number of calculators are available to estimate a patient's risk of developing breast cancer. The National Cancer Institute has an online version of the Breast Cancer Risk Assessment Tool (*www.cancer.gov/bcrisktool/Default.aspx*). This tool is based on a statistical model known as the Gail Model, derived from data from the Breast Cancer Detection and Demonstration Project, a mammography screening project conducted in the 1970s. The Breast Cancer Risk Assessment Tool was designed for healthcare professionals to project a woman's individualized risk for invasive breast cancer over a 5-year period and over her lifetime. This model has been shown to provide accurate estimates in white women, but it has not been validated for other racial and ethnic groups, and other subgroups including those with genetic risk factors. Other risk assessment models also exist, each taking into account different risk factors. Gail and colleagues have developed a similar model for assessing the risk of developing breast cancer in African-American women.[8] These empiric models may not be as useful for women with a history suggestive of hereditary breast cancer. Thus, no one model is appropriate for every patient.

ENDOCRINE FACTORS

A number of endocrine factors have been linked to the incidence of breast cancer.[9,10] Many of these relate to the total duration of menstrual life. Early menarche, generally defined as menstruation beginning before age 12 years, increases the cumulative lifetime risk of breast cancer development. Similarly, most studies demonstrate an increased risk in women with a late age of natural menopause (age 55 years or later). Conversely, bilateral oophorectomy prior to age 40 years reduces the relative risk of developing breast cancer.

Nulliparity and a late age at first birth (≥30 years) are reported to increase the lifetime risk of developing breast cancer. It is suggested that the period between the onset of menses and the age of first pregnancy provides a "window of initiation" for the development of breast cancer. This is a time when an unbalanced hormonal environment reacts with the abundant and highly responsive breast tissue. Investigators postulate that international differences in age of menarche, age at menopause, and childbearing may account for a substantial part of the international differences in the incidence of breast cancer.

Many studies have evaluated the relationship between exogenous hormones and development of breast cancer. Postmenopausal estrogen replacement therapy has been the subject of several epidemiologic studies and meta-analyses, with conflicting results. The NCI-sponsored Women's Health Initiative (WHI) is a set of clinical trials designed to investigate the risks and benefits of treatment strategies that could affect women's health issues, such as breast cancer. The WHI trials of hormone therapy were two large parallel, randomized, double-blind, placebo-controlled trials that evaluated estrogen plus progestin in combination or estrogen alone in post-menopausal women. The estrogen plus progestin trial randomized more than 16,000 postmenopausal women to take conjugated equine estrogen combined with medroxyprogesterone or a placebo.[11] This study reported an increased risk of breast cancer (38 vs 30 cases per 10,000 person-years [RR = 1.26; 95% confidence interval (CI), 1.00-1.59]) in women taking combined estrogen/progestin for an average of 5.2 years when compared to those receiving placebo. Analysis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) registries showed that the age-adjusted incidence rate of breast cancer in women in the United States in 2003 fell by 6.7% compared to 2002.[12] This decrease in breast cancer incidence seems to be temporally associated with the first report of the WHI study and subsequent decrease in estrogen and progestin hormone replacement therapy use among postmenopausal women. In the estrogen alone trial, over 10,000 women who had a hysterectomy and therefore did not require progestin therapy due to a decreased risk of endometrial carcinoma, were randomized to estrogen alone or placebo.[13] The risk of breast cancer was not increased in women who received estrogen alone as compared to placebo. Differences in dosages, formulations, and routes of administration of various hormonal preparations available make interpretation of these studies complex. However, most of the current evidence does show a causal relationship between HRT and breast cancer.[14] Unresolved issues remain as to whether lower doses or short-term use for menopausal symptoms can be safe and effective. Longer duration of use of HRT and concurrent use of progestins appear to contribute to breast cancer risk.

The use of postmenopausal HRT in women with a history of breast cancer is generally contraindicated. Because of the association of estrogen and risk of breast cancer, many clinicians believe that patients with a strong family history or other risk factors for breast cancer should not receive postmenopausal HRT. Women who are considering HRT should carefully consider the risks versus benefits (see Chap. 91 for a detailed discussion of hormone replacement therapy).

Epidemiologic studies of oral contraceptives do not show a consistent relationship between use of birth control pills and breast cancer risk. Results are conflicting and assessment of the studies should consider the particular oral contraceptive products involved, daily and cumulative doses of the hormones administered, and the latency for development of breast cancer. Newer formulations of oral contraceptives contain lower hormone concentrations, with different routes of administration (e.g., patch, injections, etc.). Reassuring data that oral contraceptives do not increase breast cancer risk later in life have recently been published.[15,16] It is also important to note that oral contraceptives are known to reduce the risk of ovarian and endometrial cancers. Although it is not entirely possible to rule out a promotional effect of oral contraceptives on breast cancer development in young patients, most experts believe that the safety and benefits of low-dose oral contraceptives currently outweigh the potential risks.

GENETIC FACTORS

Both personal and family histories influence a woman's risk of developing breast cancer. A past medical history of breast cancer is associated with an increased risk of contralateral breast cancer. Cancer of the uterus and ovary is also associated with an increased risk for the development of breast cancer. Breast cancer is also observed as part of cancer family syndromes in association with other tumors.

Many women have "lumpy breasts" and have a clinical diagnosis of fibrocystic breast disease or benign breast disease. Fibrocystic disease encompasses a heterogeneous group of processes with various degrees of breast cancer risks, and therefore is not clinically meaningful for counseling patients regarding individual risk of breast cancer. Benign breast conditions are classified as nonproliferative, proliferative without atypia, or atypical hyperplasia. Nonproliferative lesions, such as cysts or simple fibroadenomas, do not increase the risk of breast cancer. Proliferative lesions without atypia, such as intraductal papillomatosis, are associated with a mildly elevated breast cancer risk of about 1.5 to 2.0 times the general population. Atypical hyperplasias are classified as either ductal or lobular units, and these lesions may increase a woman's risk for breast cancer to about 4.5 to 5.0 times the general population.[17]

Dense breast tissue reduces the sensitivity of mammography for detecting breast cancer, and is also associated with an increased

risk of breast cancer. Genetic factors may play a role in this finding because mammographic breast density has been shown to have high heritability and is also strongly associated with a positive family history of breast cancer. Many variables including age, weight, menopausal status, HRT, and parity can influence mammographic breast density. The risk of breast cancer in women with dense breasts (defined by mammography) has been estimated to be between 2 and 6 times that of women of the same age with little density.[18]

It has been recognized for some time that a family history of breast cancer is associated with a woman's own risk for developing the disease. The percentage of all breast cancers in the population that can be attributed to family history is approximately 10%. Empirical estimates of the risks associated with particular patterns of family history of breast cancer indicate the following:[19]

1. Having any first-degree relative with breast cancer increases a woman's risk of breast cancer about 1.5- to 3-fold. Risk increases with increasing numbers of affected first-degree relatives.
2. The risk is affected by both a woman's own age and the age of the relative when diagnosed. A higher RR is seen when a woman and her relative at diagnosis are younger than 50 years.
3. The risk associated with having any second-degree relative with breast cancer is complex, and depends on other family history patterns. However, the risk is generally lower than that of first-degree relatives.
4. Affected family members on both the maternal and the paternal sides are important to consider in evaluation of risk.

Although women with a family history of breast cancer are at increased risk for the disease, the diagnosis of breast cancer is still uncommon in young women, even with a positive family history. Although family history is an important risk factor to consider, other risk factors should also be considered as most women who develop breast cancer do not have a family history. Nonetheless, increasing knowledge about the genetics of the disease continues to add to our understanding.

In the early 1990s, pedigree analysis of 23 high-risk families for breast and ovarian cancer provided evidence for a rare autosomal dominant allele.[20] Further studies identified an abnormal gene on the long arm of chromosome 17 (17q21) in a large percentage of these hereditary breast and ovarian cancer patients. Isolation of the *BRCA1* gene was initially reported in 1994. A second breast cancer gene, called *BRCA2*, has been mapped to chromosome 13. These genes function as tumor suppressor genes, maintaining genomic integrity and DNA repair. Germ-line mutations in either *BRCA1 or BRCA2* are associated with an increased risk for breast and ovarian cancer. Compared to an average woman's 13% lifetime risk of developing breast cancer, the probability of developing breast or ovarian cancer by the age of 70 years in women with a *BRCA1* or *BRCA2* mutation is estimated to be 35% to 84% for breast cancer and 10% to 50% for ovarian cancer.[21,22] The risk of ovarian cancer is considered higher among carriers of *BRCA1* mutations than for carriers of *BRCA2* mutations.

The probability of being a *BRCA* gene-mutation carrier is related to ethnicity and family history. Particular family history patterns are associated with an increased risk, including the number of unaffected and affected family members who had breast and/or ovarian cancer, including first- and second-degree relatives; younger age (<50 years) at which breast cancer is diagnosed; the presence of bilateral breast cancer; and a history of breast cancer in a male relative. Both maternal and paternal family histories are relevant. Specific gene mutations can also be seen more often among certain ethnic groups. Jewish people of Eastern European decent (Ashkenazi Jews) have an unusually high (2.5%) carrier rate of germ-line mutations in *BRCA1* and *BRCA2* as compared to the rest of the U.S. population. Three particular *BRCA* founder mutations are most often identified in women of Jewish ancestry, obviating the need to sequence entire genes and making genetic testing less complicated.[20] For this reason, some clinicians have advocated for *BRCA1* and *BRCA2* screening for all patients of Jewish descent regardless of personal or family history of breast or ovarian cancer, although current national guidelines do not recommend this broad approach.

Since the discovery of *BRCA1* and *BRCA2*, genetic testing for mutations in these genes has become available. The question of who should receive screening for *BRCA* gene mutations is unresolved. It is estimated that clinically significant *BRCA* mutations occur at a frequency of about 1 in 500 persons in the general, non-Jewish U.S. population.[22] Risk tools to predict for the presence of a clinically significant *BRCA* mutation exist. Because many of these tools were developed from data in previously tested women with existing cancer, their applicability and effectiveness for screening in the general population are unknown. Several organizations have published recommendations on genetic susceptibility testing for individuals who meet the criteria for increased risk.[21,23,24] Testing for *BRCA1* and *BRCA2* mutations is now widely available, can be accomplished through varying methodologies, and has been directly marketed to the public.[25] Nonetheless, testing is generally recommended only when there is personal or family history suggestive of hereditary cancer, when the test can be adequately interpreted, and when results will assist with diagnosis and management. Genetic counseling is highly recommended with all genetic tests to assist individuals in making informed decisions.

The clinical significance of other unclassified variant gene mutations is unknown. Testing negative for a *BRCA* gene mutation does not necessarily rule out a hereditary form of breast cancer. In cases where there is significant personal or family history, a negative test may be considered an uninformative negative, as it may be a result of mutations undetected by currently available screening techniques, or a result of mutations in other, unidentified genes. *BRCA1* and *BRCA2* account for at least 30% of all hereditary breast cancer.[26] Other genes that have been identified as being associated with hereditary breast cancer include *TP53, CHK2, PTEN,* and *ATM*.[20]

ENVIRONMENTAL AND LIFESTYLE FACTORS

Breast cancer incidence rates vary considerably between countries, which suggests that environmental and lifestyle factors play an important role in the etiology. Compelling evidence is derived from studies of Asian women who migrated to the United States. Although the incidence of breast cancer in Asian women is quite low, the incidence of breast cancer in Asian women who were born in the United States, or who migrated from Asia to the United States, gradually increases to equal that of the white population in the same geographic area.[10]

Diet is an obvious environmental factor, and possible relationships between fat intake and steroid hormone metabolism have led to an emphasis on dietary fat as a possible etiologic agent for breast cancer. Epidemiologic data show a positive correlation between higher dietary fat intake and breast cancer risk. The correlation is stronger in postmenopausal than in premenopausal women. A low-fat diet is linked to low blood estrogen levels and lower breast cancer risk. Studies in laboratory animals provide further evidence of a relationship between dietary fat intake and breast cancer. Despite these compelling indirect data, case control and cohort studies report mixed results. In a meta-analysis of 31 case-control and 14 cohort studies on dietary fat and breast cancer, Boyd et al. reported a small but significant RR of 1.13 (95% CI, 1.03- 1.25) when comparing highest and lowest fat intake categories.[27]

Additional investigated dietary factors include food-derived heterocyclic amines, which are known carcinogens found commonly in cooked meat. Experimental and epidemiologic data suggest an association between breast cancer and the Western diet, which typically includes a large amount of cooked meats and fat. In the meta-analysis by Boyd et al., saturated fat and meat intake were also associated with a small, but significant increased risk in breast cancer.[27] Other studies have found no significant association between breast cancer and the Western diet. Effects may depend on menopausal status, as studies of premenopausal women suggest a possible increased risk.[28]

Many studies have also examined the association between breast cancer and intake of dietary fiber and micronutrients, including β-carotene, and vitamins A, C, and E. The relationship between vitamins and breast cancer is unclear. Studies of breast cancer risk in relation to fruit and vegetable intake suggest some protective effect, as they are food sources of micronutrients and fiber. A meta-analysis of 21 case-control and 5 cohort studies reported a significant reduction in breast cancer risk with higher vegetable consumption, with no significant difference seen with fruit intake.[29] Additional reviews of prospective, cohort studies reported no significant associations with either vegetable or fruit intake and breast cancer risk.[30] Thus, results of studies investigating the effects of fruit, vegetable, fiber, and meat consumption on breast cancer incidence are inconclusive.

One dietary factor that deserves mention is the possible effect of phytoestrogens on breast cancer risk. Phytoestrogens are natural plant estrogens found in soybean products, seeds, berries, and nuts. The two most studied classes of dietary phytoestrogens are isoflavones and ligands; isoflavones are richer in Asian diets and ligands are the main source of phytoestrogens in the Western diet.[31] Interest in the study of these compounds has largely been based on observational studies showing lower rates of breast cancer in Asian countries, where soy consumption is high.[32] Because these compounds exhibit weak estrogenic properties, some experts believe that they may function as relative antiestrogens by displacing natural estradiol. However, studies have also reported a potential stimulatory effect on breast tissue. A meta-analysis of observational studies which evaluated phytoestrogen use and the risk of breast cancer suggests that the associated risk reduction may be limited to postmenopausal patients.[33] Nonetheless, the effect of phytoestrogens on breast cancer is very controversial, and further research is needed.

The hypothesis that low dietary fat intake reduces breast cancer risk was tested in the WHI Randomized Controlled Dietary Modification Trial.[34] This study is the first large-scale, prospective, controlled trial to study the relationship between diet and breast cancer. It randomized more than 48,000 postmenopausal women to a dietary intervention that consisted of reducing total fat intake to 20% of energy, consuming at least five servings of fruits and vegetables daily and six servings of grains daily, versus a comparison group without any dietary interventions. Risk factors for breast cancer were evenly balanced between groups. Over an 8-year mean follow-up period, 3.35% of women in the intervention group developed invasive breast cancer versus 3.66% of women in the comparison group (annualized incidence rate, 0.42% vs 0.45%; hazard ratio [HR], 0.91; 95% CI, 0.83-1.01). Although the difference was not statistically significant, a trend toward a decreased incidence over time was seen, suggesting the need for longer follow-up. Limitations from this study include the inability to separate out the effects on breast cancer attributed to dietary fat reduction as compared to that attributed to increased fruit, vegetable, and grain intake. Because the WHI trial only evaluated women who adopted dietary changes after menopause, it is unknown what the effects would be in younger women or girls who make these dietary interventions sooner in life. Although there is still much to be learned about the effects of diet on the risk of developing breast cancer, a low-fat diet seems to be a reasonable approach to potentially reduce the risk of breast cancer.

Both body weight and height are associated with developing breast cancer. High body mass index and obesity are related to breast cancer risk in a complex way that differs by age and menopausal status. Most studies of premenopausal women show either no relationship with body weight, or slightly declining breast cancer risks with increasing body weight. One plausible biologic mechanism to explain this observation is reduced ovarian activity in obese women. Most studies in postmenopausal women, however, show increasing breast cancer risks with increasing body weight. Accordingly, a recent meta-analysis found that an increase in body mass index was associated with an increase in the risk of breast cancer for postmenopausal women (RR, 1.12; 95% CI 1.08–1.16; P <0.0001), but had the opposite effect in premenopausal women (RR, 0.92; 95% CI 0.88–0.97; P <0.001).[35] In addition to obesity, the distribution of body fat also may play an independent role in the development of breast cancer. Upper body (central or abdominal) adiposity increases the risk of breast cancer independent of overall obesity. This association may be related to the excess levels of free-circulating estrogen resulting from the conversion of androstenedione to estradiol in peripheral adipose tissue.[36] Although height is not a modifiable risk factor, weight and body composition are modifiable and should be studied further.

Many studies report an inverse association between physical activity and breast cancer risk.[37] A review of 19 cohort and 29 case-control studies suggests that the association is stronger for postmenopausal breast cancer than for premenopausal breast cancer. Exercise may provide modest protection against breast cancer, but the relationship is complex. Possible explanations include the effects of physical activity on menstrual characteristics (in premenopausal women), body size, weight, and serum hormone levels. Thus estrogen-related pathways or other metabolic hormones such as insulin or insulin-like growth factors may play a role.

Many epidemiologic studies have evaluated the relationship between alcohol and breast cancer. Alcohol is the only dietary factor that has shown consistent results in clinical trials. Studies indicate both a modest positive association between alcohol and breast cancer and a dose–response relationship.[38,39] The risk increases with consumption of alcohol in general, regardless of the beverage type or woman's menopausal status. Potential biologic mechanisms for this association include increased levels of estrogen or other reproductive steroid hormones; increased production of insulin-like growth factors by the liver; and altered hepatic metabolism of carcinogens. Although a causal relationship between alcohol consumption and breast cancer has not been proven in a prospective trial, the weight of the evidence suggests that a relationship, direct or indirect, may exist. As alcohol consumption is a modifiable risk factor, use in moderation is a sensible approach.

Radiation is associated with an increased risk of breast cancer, particularly with exposure at a young age (<20 years), which again suggests that a "window of initiation" for breast cancer occurs at a relatively early age. Much of the knowledge about radiation-related breast cancer comes from epidemiologic studies of patients exposed to diagnostic or therapeutic radiation, and of survivors of the Japanese atomic bombs.[40] Women treated with chest irradiation for childhood and adolescent Hodgkin lymphoma, as well as survivors of other childhood cancers (where radiation is used as a mainstay of therapy) are among the populations at greater risk for secondary breast cancers. The risk increases linearly with radiation dose. Exposure to diagnostic x-rays including annual screening mammography does not impart a sufficient dose of radiation for clinical concern in the general population. The risk of breast cancer after radiation exposure in those with genetic risk factors is unclear and is an ongoing area of research.

In conclusion, numerous studies have been performed to investigate potential causative factors in the etiology of breast cancer. Several endocrine, genetic, environmental, and lifestyle factors are associated with the development of breast cancer to varying degrees. Some factors are modifiable, whereas others are not. Additionally, the impact of individual risk factors may vary depending on other confounding variables such as age, family history, estrogen use, and menopausal status. Although epidemiologic studies provide a large body of the current evidence, each has its limitations and results are varied. Meta-analyses can summarize the numerous study results, but heterogeneity of studies can be a limitation. Additional prospective, randomized controlled trials will add to our knowledge of factors that affect the risk of developing breast cancer.

CLINICAL PRESENTATION

CLINICAL PRESENTATION

General

- The patient may not have any symptoms, as breast cancer may be detected in asymptomatic patients though routine screening mammography.

Local Signs and Symptoms

- A painless, palpable lump is most common.
- Less common: pain; nipple discharge, retraction or dimpling; skin edema, redness or warmth.
- Palpable local–regional lymph nodes may also be present.

Signs and Symptoms of Systemic Metastases

- Depends on the site of metastases, but may include bone pain, difficulty breathing, abdominal pain or enlargement, jaundice, mental status changes.

Laboratory Tests

- Tumor markers such as cancer antigen (CA 27.29) or carcinoembryonic antigen (CEA) may be elevated.
- Alkaline phosphatase or liver function tests may be elevated in metastatic disease.

Other Diagnostic Tests

- Mammogram (with or without ultrasound, breast MRI, or both).
- Biopsy for pathology review and determination of tumor estrogen/progesterone receptor (ER/PR) status and *HER2* status.
- Systemic staging tests may include: chest x-ray, chest CT, bone scan, abdominal CT or ultrasound, or MRI.

A painless lump is the initial sign of breast cancer in most women. The typical malignant mass is solitary, unilateral, solid, hard, irregular, and nonmobile. In small numbers of cases, stabbing or aching pain is the first symptom. Less commonly, nipple discharge, retraction, or dimpling may herald the onset of the disease. In more advanced cases, prominent skin edema, redness, warmth, and induration of the underlying tissue may be observed.

The breast is a complex organ composed of skin, subcutaneous tissue, fatty tissue, and branching ductal and glandular structures (Fig. 136–2). Various diseases that affect these structures can produce a palpable mass. In addition, the physiologic changes associated with the menstrual cycle can cause breast abnormalities. Common causes of breast masses in young women are fibroadenoma, fibrocystic disease, carcinoma, and fat necrosis.

Many women will detect some breast abnormality themselves, underscoring the importance of breast self-examination. But in the United States, it is increasingly common for breast cancer to be detected during routine screening mammography in asymptomatic women. It is widely accepted that the smaller the mass, the higher the likelihood of cure. Thus as the number of breast cancer cases found by screening mammography increases, overall survival of breast cancer patients has improved, albeit this decreasing mortality is also related to improved systemic therapy.

Breast cancer that is confined to a localized breast lesion is often referred to as *early*, *primary*, *localized*, or *curable*. Breast cancer that has spread to local-regional lymph nodes is still considered early stage (Fig. 136–3). Unfortunately, breast cancer cells often spread by contiguity, lymph channels, and through the blood to distant sites. This often occurs early in breast cancer growth, and deposits of tumor cells form in distant sites that cannot be detected with current diagnostic methods and equipment (micrometastases). When breast cancer cells can be detected clinically or radiologically in sites distant from the breast, the disease is referred to as *advanced* or *metastatic* breast cancer. Tissues most commonly involved with metastases are lymph nodes (other than local–regional lymph nodes), skin, bone, liver, lungs, and brain. Symptoms of bone pain, difficulty breathing, abdominal enlargement, jaundice, and mental status changes may herald the clinical presentation of metastatic breast cancer. A small percentage of women have signs and symptoms of distant metastases when they first seek treatment. In virtually all of them, a breast mass has been present for several months to years. In addition, about one half of all patients who initially are treated for localized disease will eventually develop signs and symptoms of metastatic breast cancer.

DIAGNOSIS

Initial workup for a woman presenting with a lesion or symptoms suggestive of breast cancer should include a careful history, physical examination of the breast, 3-D mammography, and possibly other breast imaging techniques such as ultrasonography or MRI. Most breast cancers can be visualized on a mammogram as a mass, a cluster of calcifications, or a combination. Specific mammographic features associated with the highest risk of malignancy include masses with spiculated margins and/or irregular shape, and calcifications with a linear and/or segmental distribution.[41] Factors that affect the ability of mammography to detect cancer include breast density (the fat-to-glandular tissue ratio of the breast) which may be affected by age, menopausal status, and HRT. Ultrasonography, MRI, and digital mammography are alternate breast imaging methods that are being investigated for women with dense breasts or other specific subsets of patients with breast cancer (e.g., MRI in patients with inflammatory breast cancer).[42] The technical quality of the examination and the expertise of the radiologist are also important factors.

The Breast Imaging Reporting and Data System (BI-RADS) was developed by the American College of Radiology to standardize mammographic reporting.[43] Table 136–2 lists the BI-RADS classifications for standardized reporting for mammography. There are seven assessment categories with four possible recommendations: (a) additional imaging evaluation, (b) routine interval screening, (c) short-term follow-up, and (d) biopsy. The probability of a biopsy positive for malignancy increases from <2% for BI-RADS category 3 mammograms to 20% to 30% for category 4 mammograms, to >95% for category 5 mammograms. Similar categories for reporting have also been developed for breast MRI and ultrasonography.

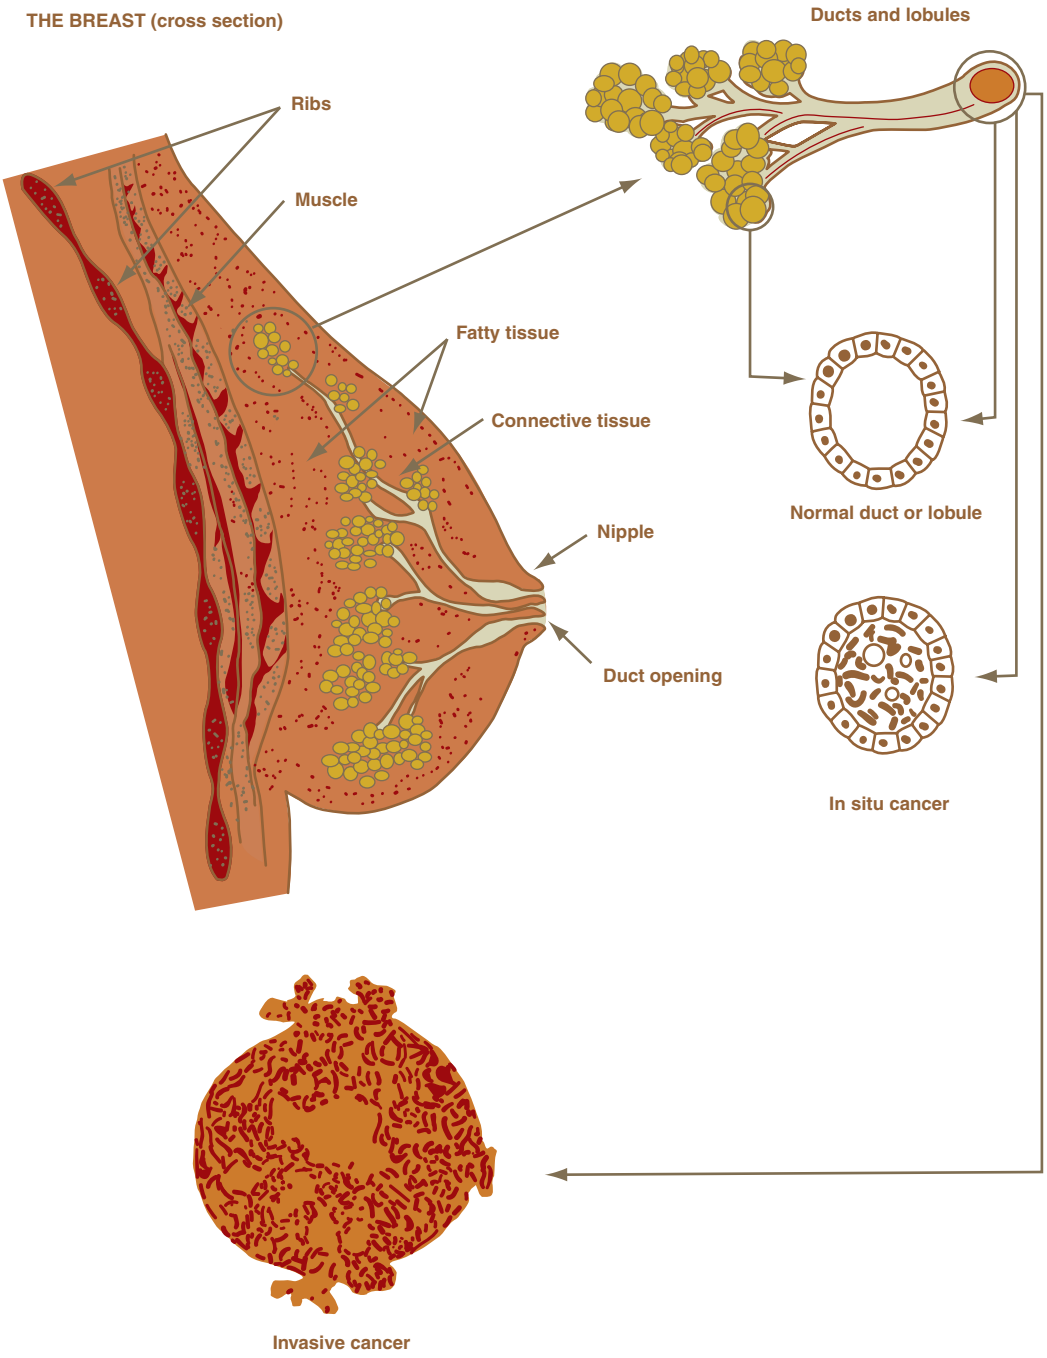

FIGURE 136-2. Breast anatomy.

Breast biopsy is indicated for a mammographic abnormality that suggests malignancy or for a palpable mass on physical examination. Three techniques are available: fine-needle aspiration, core-needle biopsy, and excisional biopsy.[44] Excisional biopsy, which completely removes the abnormal tissue, is performed with either a local or general anesthetic, and is usually done as an outpatient operative procedure. Needle biopsies are performed percutaneously, and include both core-needle biopsy (which removes a core of tissue) and fine-needle aspiration (which removes cells from the suspicious site). These are generally office procedures that are associated with minimal discomfort and anxiety, few complications, no disfigurement, and decreased costs when compared to surgical excisional biopsy. The accuracy of fine-needle aspiration is good in experienced hands, but its limitations include false negatives, specimens with insufficient material for diagnosis, and the inability to distinguish invasive from in situ cancer. Core-needle biopsy is the preferred biopsy method for mammographically detected, nonpalpable abnormalities.[42] Core-needle biopsy offers a more definitive histologic diagnosis, avoids inadequate samples, and can distinguish invasive from in situ breast cancer. Following confirmation of malignancy via core-needle biopsy, subsequent surgical procedures are performed to assure complete removal of the abnormal tissue.

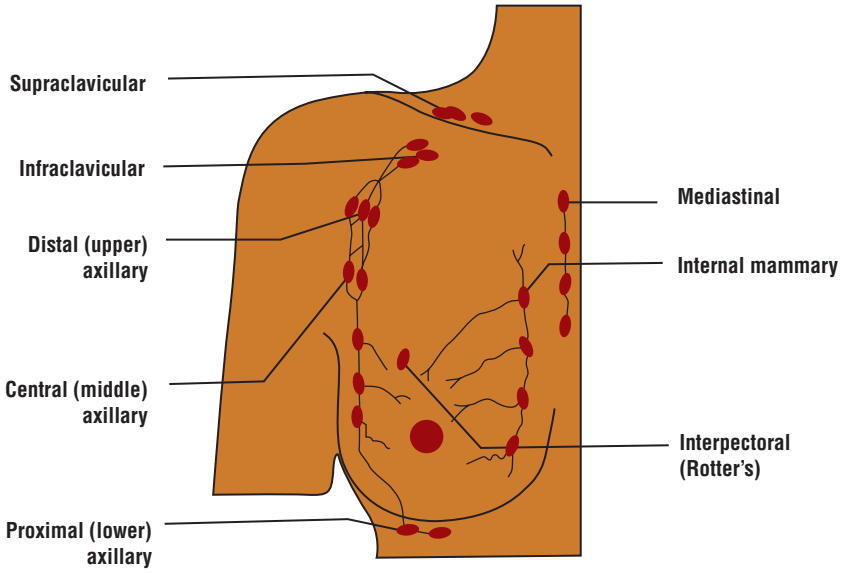

FIGURE 136-3. Lymph node anatomy.

STAGING AND PROGNOSIS

Few malignant diseases illustrate the importance of the relationship of stage (anatomic extent of disease) at the time of diagnosis and overall survival more clearly than breast cancer. Stage is defined on the basis of the primary tumor extent and size (T_{1-4}), presence and extent of lymph node involvement (N_{1-3}), and presence or absence of distant metastases (M_{0-1}) (Table 136–3 and Fig. 136–4). Although many possible combinations of T and N are possible within a given stage, simplistically, stage 0 represents carcinoma in situ (T_{is}) or disease that has not invaded the basement membrane of the breast tissue. Stage I represents a small primary invasive tumor without lymph node involvement or with micrometastatic nodal involvement, and stage II disease usually involves regional lymph nodes. Stages I and II are often referred to as *early breast cancer*. It is in these early stages that the disease is highly curable. Stage III, also referred to as *locally advanced disease*, usually represents a large tumor with extensive nodal involvement in which either node or tumor is fixed to the chest wall. Stage IV disease is characterized by the presence of metastases to organs distant from the primary tumor and is often referred to as *advanced or metastatic disease* as described earlier. Most breast cancer today presents in early stages where the prognosis is favorable (Table 136–4).

Staging for breast cancer is separated into two groups, clinical and pathologic. Clinical staging is assigned prior to surgery and is based on physical exam (assessment of tumor size and presence of axillary lymph nodes), imaging (mammogram, ultrasound, etc.), and pathologic examination of tissues. Pathologic staging occurs after surgery and uses information from clinical staging, but adds data from surgical exploration and resection, such as tumor size at surgery and the involvement of micro- or macro-invasive tumor in the lymph nodes or other metastatic sites. Due to the advent of sentinel lymph node biopsy (SLNB; see Treatment of Early Breast Cancer section), the assessment of lymph node status has become more complex. The

TABLE 136-2 Breast Imaging Reporting and Database System (BI-RADS®) Assessment Categories for Mammography

Category	Assessment
a. Assessment is Incomplete	
0	Need Additional Imaging Evaluation and/or Prior Mammograms for Comparison
b. Assessment is Complete – Final Categories	
1	Negative
2	Benign Finding(s)
3	Probably Benign Finding – Initial Short-Interval Follow-Up Suggested
4	Suspicious Abnormality – Biopsy Should Be Considered
5	Highly Suggestive of Malignancy – Appropriate Action Should Be Taken
6	Known Biopsy-Proven Malignancy – Appropriate Action Should Be Taken

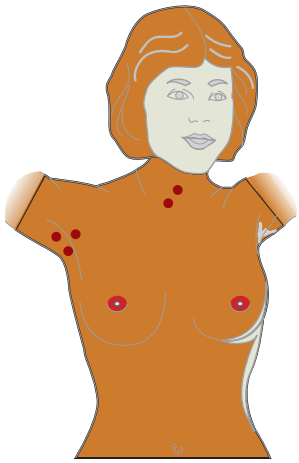
Tumor (T)

- T_x Primary tumor cannot be assessed
- T_0 No evidence of tumor
- T_{is} Carcinoma in situ
- T_1 ≤2 cm
  - T_1 mic ≤0.1 cm
  - T_{1a} > 0.1–0.5 cm
  - T_{1b} > 0.5–1 cm
  - T_{1c} > 1–2 cm
- T_2 >2–5 cm
- T_3 >5 cm
- T_4 Any size; with direct extension to chest wall or skin
- T_{4a} Extension to chest wall (not including pectoralis muscle)
- T_{4b} Edema (including peau d'orange) or ulceration of skin or satellite skin nodules
- T_{4c} Both T_{4a} and T_{4b}
- T_{4d} Inflammatory carcinoma



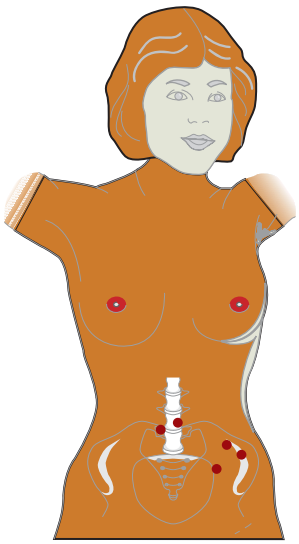
Clinical Nodes (N)

- N_X Regional lymph nodes cannot be assessed (e.g., previously removed)
- N_0 No regional lymph node metastasis
- N_1 Metastasis in movable ipsilateral axillary lymph node(s)
- N_2 Metastases in ipsilateral axillary lymph nodes fixed or matted, or in clinically detected ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
  - N_{2a} Metastasis in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
  - N_{2b} Metastasis only in clinically detected ipsilateral internal mammary nodes and in the absence of clinically evident axillary lymph node metastasis
- N_3 Metastasis in ipsilateral infraclavicular lymph node(s), or in clinically detected ipsilateral internal mammary lymph node(s) and in the presence of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
  - N_{3a} Metastasis in ipsilateral infraclavicular lymph node(s) and axillary lymph node(s)
  - N_{3b} Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
  - N_{3c} Metastasis in ipsilateral supraclavicular lymph node(s)

Pathologic Nodes (pN)[†]

- pN0 No regional lymph node metastasis histologically
- pN1mi Micrometastasis (>0.2 mm but none >2.0 mm)
- pN1 Metastasis in one to three axillary lymph nodes and/or internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically detected
- pN2 Metastasis in four to nine axillary lymph nodes, or in clinically detected internal mammary lymph nodes in the absence of axillary lymph node metastasis
- pN3 Metastasis in 10 or more axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically detected ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes; or in more than three axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral supraclavicular lymph nodes

[†]Based on axillary lymph node dissection with or without sentinel lymph node dissection



Metastasis (M)

- M_X Distant metastasis cannot be assessed
- M_0 No distant metastases
- M_1 Distant metastasis

American Joint Committee for Cancer (AJCC) publishes staging criteria for cancers and the breast cancer criteria were updated and officially implemented in January 2010.[45] Tumor staging systems are periodically updated to incorporate new diagnostic and therapeutic advances that affect risk of disease recurrence and survival. One of the major changes in the 2010 staging system updated from the 2003 version is the designation of new substages, IA and IB. Other subtle, yet important differences are noted. However, these are complex and well beyond the scope of this chapter. The reader is referred to the AJCC manual for details.[45] This staging system is widely accepted and used in all breast cancer patients to determine prognosis and assist with treatment decisions.

PATHOLOGY

The pathologic evaluation of breast lesions serves to establish the histologic diagnosis and to confirm the presence or absence of other factors believed to influence prognosis.

INVASIVE CARCINOMA

Invasive breast cancers are a histologically heterogeneous group of lesions. Most breast cancers are adenocarcinomas and are classified on the basis of their microscopic appearance as ductal or lobular, corresponding to the ducts and lobules of the normal breast (Fig. 136–2). The various histologic types of breast cancer have different prognoses, but it is unknown whether their response to therapy differs, because patients in therapeutic trials are not typically stratified according to histologic type. The five most common types of invasive breast cancer are briefly described.[46]

Invasive or *infiltrating ductal carcinoma* is the most common histology. These tumors are generally referred to as infiltrating ductal carcinoma "not otherwise specified," and account for approximately 75% of all invasive breast cancers. These tumors commonly spread to the axillary lymph nodes and their prognosis is poorer than for other histologic types (specifically tubular, medullary, and mucinous). *Invasive or infiltrating lobular carcinoma* accounts for 5% to 10% of breast tumors. Both clinical and radiologic findings for these tumors may be quite subtle. Typical presentation is an area of ill-defined thickening in the breast, in contrast to a prominent lump characteristic of infiltrating ductal carcinoma. *Infiltrating lobular carcinoma* can also be more difficult to detect by mammography. Overall, *infiltrating lobular carcinoma* and *infiltrating ductal carcinoma* have similar likelihoods of axillary node involvement and disease recurrence and death, yet the sites of metastases tend to differ. *Infiltrating ductal carcinoma* more frequently metastasizes to the bone or to the liver, lung, or brain, whereas *infiltrating lobular carcinoma* tends to metastasize to the leptomeninges, peritoneal surfaces, retroperitoneum, gastrointestinal tract, reproductive organs, and other unusual sites.

The three most common special types of invasive cancer are *medullary*, *mucinous*, and *tubular*. Prognosis may be more favorable with these unusual histologies. *Medullary carcinoma* accounts for less than 7% of all breast carcinomas, *mucinous (or colloid) carcinoma* constitutes approximately 3%, *and tubular carcinoma* accounts for approximately 2% of all breast cancers. Histologies rarely reported include adenocystic carcinoma, carcinosarcomas, metaplastic, cribriform, and papillary carcinoma.

Special situations seen clinically and histologically include Paget's disease of the breast, phyllodes tumors, and inflammatory breast cancer. Paget's disease of the breast occurs in 1% to 4% of all patients with breast cancer, and is characterized by neoplastic cells in the nipple areolar complex. The patient presents clinically with eczematous changes in the nipple with itching, burning, oozing, bleeding, or some combination of these. In most cases, the nipple changes are associated with an underlying carcinoma in the breast that is usually palpable.

Phyllodes tumors of the breast (also known as cystosarcoma phyllodes) are rare tumors with subtypes that range from benign to malignant. These tumors often enlarge rapidly, are painless, and can appear radiographically as fibroadenomas.[47]

Inflammatory breast cancer is characterized clinically by prominent skin edema, redness and warmth, and induration of the underlying tissue. Biopsies of the involved skin reveal cancer cells in the dermal lymphatics. Inflammatory breast cancer typically has a very rapid onset and is often mistaken for an infectious cellulitis or mastitis. Although it may look somewhat similar to a neglected mass, its presentation with rapid onset and progression of local symptoms distinguishes it from other cases of locally advanced breast cancer. Prognosis of patients with inflammatory breast cancer is poor, even if the disease is apparently localized.[48]

NONINVASIVE CARCINOMA

As with invasive carcinoma, the noninvasive lesions may be divided broadly into ductal and lobular categories. Evidence supports that the development of malignancy is a multistep process and that invasive breast cancer has a preinvasive phase. During the carcinoma in situ phase, normal epithelial cells undergo genetic alterations that result in malignant transformation. Transformed epithelial cells proliferate and pile up within lobules or ducts, but lack the required genetic alterations that enable the cells to penetrate the basement membrane. Therefore carcinoma in situ is diagnosed when malignant transformation of cells has occurred, but the basement membrane is intact.

The widespread use of screening mammography and subsequent biopsy and greater recognition of noninvasive breast carcinoma by pathologists has resulted in a significant increase in the diagnosis of in situ breast cancer during the past decade. Assuming consistent incidence and survival rates, researchers estimate that the prevalence of breast in situ cancers will exceed 1 million cases by 2016.[49] The natural history of these disorders is not well described, and thus the debate continues regarding carcinoma in situ: Is carcinoma in situ preinvasive cancer or simply a marker of unstable epithelium that represents an increased risk for the development of subsequent aggressive cancer?[50,51]

DCIS is more frequently diagnosed than lobular carcinoma in situ (LCIS). Most cases of DCIS today are found by biopsies performed for clustered microcalcifications seen on screening mammography. Five distinct histologic patterns of DCIS have been identified: comedo, cribriform, micropapillary, papillary, and solid.

The ultimate goal of treatment for noninvasive carcinomas is to prevent the development of invasive disease. If left untreated, it is

estimated that 14% to 50% of DCIS lesions will progress to invasive breast cancer.[52] Treatment of DCIS depends on its location, size, and pathology.[47] Treatment options include: (1) local excision alone with negative margins; (2) local excision (with negative margins) followed by breast irradiation; and (3) traditional total mastectomy with or without reconstruction. Whole breast irradiation is recommended following excision to significantly decrease the risk of local recurrence, although there is no evidence that survival differs between the previously mentioned options.[47] Excision with negative margins alone, without radiation may be considered in patients with small and low-grade DCIS. Mastectomy had been the standard treatment of DCIS for several decades, but long-term survival appears to be equivalent with mastectomy versus excision and irradiation, and the latter option allows for breast conservation. If more than one area of the breast is involved with DCIS, a mastectomy is the preferred option. It has also been suggested that breast conservation may not be appropriate for younger women whose lifetime risk of breast cancer is high given a diagnosis of DCIS, including *BRCA1* or *BRCA2* mutation carriers. Axillary lymph node dissection is generally not indicated, although sentinel lymph node biopsy (see Early Breast Cancer section) may be considered in selected patients.[47] Patients with invasive disease found at the time of surgery should be treated according to guidelines for patients with early stage invasive breast cancer.[47] Currently cytotoxic chemotherapy has no role in the treatment of patients with pure DCIS. It is important to determine tumor hormone receptor status because tamoxifen treatment for 5 years may be considered in some women with DCIS. The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-24 trial, which randomized women with DCIS to lumpectomy with radiation plus either tamoxifen or placebo, showed a benefit with tamoxifen in reducing ipsilateral breast cancer recurrence (44% reduction; $P = 0.03$).[53] Further subgroup analyses of this trial suggest a benefit for those patients with estrogen receptor-positive DCIS. Ongoing clinical trials are evaluating the role of aromatase inhibitors in the treatment of postmenopausal DCIS. Follow-up of women who have been treated for DCIS should be as comprehensive as that of a woman with invasive carcinoma to facilitate early detection of subsequent malignancy.[51]

LCIS is a microscopic diagnosis because there is no palpable mass and no specific clinical abnormality. Unlike DCIS, LCIS does not generally demonstrate calcifications on mammography, and in fact is usually undetectable by mammography. Consequently, the diagnosis of LCIS is usually an incidental finding in biopsy specimens obtained because of symptoms or mammography findings consistent with benign lesions. It is unclear whether LCIS is a precursor lesion to invasive carcinoma or serves as a marker of risk for invasive carcinoma developing somewhere in the breast. The risk for developing invasive carcinoma is approximately 0.5% to 1% per year, and both invasive ductal carcinoma and invasive lobular carcinoma can occur. In approximately 30% to 50% of patients, there are multiple foci of LCIS in the ipsilateral breast, and the contralateral breast is also affected. Thus the risk for the development of breast cancer is equally high in either breast, which makes the management of LCIS very controversial.[50] Some experts favor a program of observation, with semiannual physical examination and annual mammography.[47] In selected patients with high-risk genetic mutations or strong family history, or in women who are particularly anxious about the development of cancer, bilateral mastectomies with or without reconstruction may be considered.[54] Radiation and systemic chemotherapy have no role in the management of LCIS. The use of chemoprevention with tamoxifen in premenopausal women or tamoxifen or raloxifene in postmenopausal women can be considered as an option for risk reduction. Patients with LCIS were included in both the NSABP Breast Cancer Prevention Trial (P1) and the Study of Tamoxifen and Raloxifene (P2) trials.[55,56] Both trials showed approximately a 50% reduction in the risk of developing invasive breast cancer for women with LCIS receiving either tamoxifen or raloxifene (see Prevention and Early Detection below).

PROGNOSTIC FACTORS

The natural history of breast cancer varies between patients, with some having an extremely aggressive disease that progresses rapidly, whereas others follow a more indolent course. The ability to predict prognosis is extremely important in designing treatment recommendations to maximize quantity and quality of life. A number of pathologic prognostic and predictive factors have been identified. Prognostic factors are characteristics or measurements available at diagnosis or time of surgery, that in the absence of adjuvant therapy are associated with recurrence rate, death rate, or other clinical outcomes. Predictive factors are measurements available at diagnosis that are associated with response to a specific therapy. Prognostic and predictive factors fall into three categories: patient characteristics that are independent of the disease such as age; disease characteristics such as tumor size or histologic type; and biomarkers that are measurable parameters in tissues, cells, or fluids, such as hormone receptor status.[51,52] Ideally, the use of prognostic and predictive factors can limit a specific treatment to patients who are most likely to derive benefit, thus sparing unwanted toxicities in those who are unlikely to benefit.

Age at diagnosis and ethnicity are patient characteristics that may affect prognosis. Some younger patients, particularly those younger than 35 years of age, have more aggressive forms of disease and a worse prognosis. Younger patients are more likely to present with poor prognostic features, such as affected lymph nodes, large tumor size, and tumors negative for hormone receptors. Race and ethnicity may also play a role in breast cancer prognosis. African American women have decreased survival compared to white women. The cause of this racial disparity is widely debated, with possible explanations including access to care, socioeconomic status, cultural differences, higher stage at diagnosis, and more aggressive biologic features.

Potentially modifiable prognostic factors include alcohol use, dietary factors, and exercise. Kwan and colleagues found that alcohol use (>6 g/day) increases the risk of recurrence and breast cancer death in patients with a personal history of breast cancer, primarily in postmenopausal and obese women.[57] Diet may also play an important role in breast cancer recurrence. In the Women's Healthy Eating and Living (WHEL) trial, 3,088 pre- and postmenopausal women previously treated for early stage breast cancer were randomized to: group 1, a diet rich in vegetables (five servings of vegetables plus 16 oz vegetable juice), fruits (three servings), and fiber (30 g) and low in fat (15%–20% of energy intake from fat) or; group 2, a five-a-day diet (five servings of fruits and vegetables, more that 20 g of fiber, and less than 30% of total energy intake from fat).[58] After a 7.3 year follow-up period, the group 1 diet did not reduce breast cancer events or mortality compared to the group 2 diet. In a second trial by Chlebowski and colleagues, a low-fat diet (goal of reducing percentage of fat to 15%) improved relapse-free survival in women with early stage, resected breast cancer compared to a control group, although the results were not statistically significant (HR, 0.76; 95% CI, 0.60-0.98; $P = 0.077$). Interestingly, in women with ER-negative breast cancer, a low-fat diet significantly improved relapse-free survival compared to the control group (HR 0.58; 95% CI, 0.37-0.91; $P = 0.018$). Although there is still much to be learned about the effects of diet on the risk of developing breast cancer, a low-fat diet may reduce the risk of recurrence and improve relapse-free survival in women with early stage, resected breast

TABLE 136-5 Five-Year Survival Rates (%) According to Tumor Size and Axillary Lymph Node Status

	Tumor Size		
Lymph Node Status	***<2 cm***	***2–5 cm***	***>5 cm***
Negative	96	89	82
1–3 positive	87	80	73
≥4 positive	66	59	46

Data from Schnitt SJ, Guidi AJ. Pathology of invasive breast cancer. In: Harris JR, Lippman ME, Morrow M, Osborne CK, eds. Diseases of the Breast, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2004:567.

cancer, especially in patients with ER negative disease.[59] Exercise in women following a diagnosis of breast cancer may also increase the likelihood of overall survival.[60] Based on these data, agencies such as the American Cancer Society have recognized that physical activity, weight control, and diet are potentially modifiable risk factors for reducing the risk of recurrent breast cancer and other comorbidities (e.g., heart disease, diabetes).[61]

Disease characteristics that have been shown to provide important prognostic information include lymph node status, tumor size, histologic subtype, nuclear or histologic grade, lymphatic and vascular invasion, and proliferation indices.

Tumor size and the presence and number of involved lymph nodes are established primary factors in assessing the risk for breast cancer recurrence and subsequent metastatic disease. Table 136–5 shows 5-year survival rates according to size of the primary tumor and axillary node involvement. The major factor that influences the likelihood of recurrence is the presence of positive lymph nodes. However, regardless of lymph node status, the size of the primary tumor remains an independent prognostic factor for disease recurrence.

The number of affected lymph nodes is directly related to disease recurrence. The revised staging system for breast cancer recognizes the absolute number of positive nodes as a prognostic factor: N_1 represents 1 to 3 positive nodes, N_2 represents 4 to 9 positive nodes, and N_3 represents 10 or more positive nodes in its pathologic staging system.[45]

Certain histologic subtypes and clinical presentation of breast cancer have prognostic importance. As mentioned earlier, because women with pure *tubular* or *mucinous* tumors have more favorable outcomes than *invasive ductal carcinomas*, treatment recommendations may differ.[47] Inflammatory breast cancer, although a clinical designation and not a distinct histologic subtype, is associated with a poor prognosis.

Nuclear grade and tumor (histologic) differentiation are known independent prognostic indicators. Several histologic grading systems have been developed, most of which grade tumors with a score from 1 to 3: grade 1 (well differentiated); grade 2 (moderately differentiated); grade 3 (poorly differentiated). Higher-grade tumors are associated with higher rates of distant metastasis and poorer survival. This factor aids in making treatment decisions, particularly for patients with small tumors and negative lymph nodes.

Lymphatic and vascular invasion, defined as evidence of tumor emboli in lymphatic or vascular spaces, has emerged in recent years as having prognostic significance for the risk of recurrence. This factor helps identify node-negative patients who are at increased risk for lymph node involvement and metastases. However, in at least one prospective evaluation of more than 15,000 patients with early stage breast cancer, lymphovascular invasion was not associated with shorter disease-free interval or overall survival in patients categorized as low-risk for the development of breast cancer recurrence.[62]

The rate of tumor cell proliferation also has prognostic significance for breast cancer recurrence. Rate of cell proliferation can be evaluated with various techniques, including mitotic index, which counts the number of mitotic bodies; thymidine-labeling index or S-phase fraction with DNA flow cytometry, which determines the percentage of tumor cells actively dividing; or through the use of monoclonal antibodies to antigens present on proliferating cells, such as Ki-67. In a meta-analysis which included 85 studies and nearly 33,000 patients, proliferation markers (including Ki-67, mitotic index, proliferating cell nuclear antigen, and thymidine or bromodeoxyuridine labeling index) were associated with significantly shorter disease-free and overall survival.[63] These proliferation indices are additional factors that may be useful in decision making, and may also be predictive markers for responsiveness to chemotherapy, although this is still controversial.

Hormone receptors are not strong prognostic markers, but are used clinically to predict response to hormone therapy. Hormone receptors are nuclear transcription factors that, upon ligand binding, activate a variety of signal transduction pathways that result in cell growth and proliferation. The hormone receptors clinically useful in discussions of breast cancer include the estrogen receptor (ER) and the progesterone receptor (PR). Determination of both ER and PR status is an established procedure that is important in the management of breast cancer. Immunohistochemistry is used to determine the level (i.e., quantity) of hormone receptors, which is important for predictive ability. A more recent method of determining ER and PR status involves using gene-based assays which measure mRNA expression and is able to quantitate the amount of ER (or PR) protein present on cancer cells. These new methods have not been validated as predictive tools for treatment decisions. However, a great deal of investigation is ongoing looking into this type of application. Although the ER has received the most attention, presence of the PR protein is important for the functional effects of the ER protein to occur. Hormone receptors are most valuable in predicting response to hormone therapy. Approximately 60% to 70% of patients with ER-positive and PR-positive tumors will respond to hormonal manipulation. Patients with ER-negative and PR-negative tumors rarely respond to hormonal manipulation. The response rate in patients with ER-positive and PR-negative or ER-negative and PR-positive tumors is somewhere in between, but significant benefit may still be gained with hormonal therapy in these patients.

Approximately 50% to 70% of patients with primary or metastatic breast cancer have hormone receptor-positive tumors. Hormone receptor positivity, more common in postmenopausal women, is associated with a superior response to hormone therapy and a longer disease-free survival.

The *HER2/neu (HER2)* gene is located on chromosome 17q21 and encodes a 185-kilodaton transmembrane tyrosine kinase growth factor receptor. The *HER2* protein is normally expressed at low levels in the epithelial cells of normal breast tissue. *HER2* is a member of the erbB (or HER) growth factor receptor family and its overexpression is associated with transmission of growth signals that control aspects of normal cell growth and division. *HER2* overexpression occurs in approximately 20% to 30% of breast cancers, and is associated with increased tumor aggressiveness, increased rates of recurrence, and increased mortality. In some studies, *HER2* gene amplification and protein overexpression, measured by fluorescence in situ hybridization (FISH) and immunohistochemistry (IHC), respectively, correlates with factors associated with a poor prognosis. Clearly, a *HER2*-positive status predicts response to trastuzumab therapy, which is a monoclonal antibody directed against the extracellular domain of the *HER2* receptor. A final controversy surrounds the testing method employed to determine *HER2* status. Although there are many methods, *HER2* gene amplification measured by FISH (reported as either positive, equivocal, or negative) and overexpression of the *HER2* protein product measured by IHC (reported as 0, 1+, 2+, or 3+) are the most commonly used methods.

HER2 status should be determined for all invasive breast cancers, and guidelines for testing are available.[64] Tumors that are either IHC 3+ or FISH positive for gene amplification are considered to be positive for *HER2*. Some have argued that *HER2* testing by FISH should be the primary method of determining *HER2* positivity, based on technical limitations of IHC testing as well as other reasons.[65] However, FISH testing is not always available and may require sending tissue to an outside laboratory. Therefore, both methods are acceptable for predicting response to *HER2*-targeted therapy. For equivocal results of IHC (2+) or FISH, confirmatory testing with the alternate test is recommended. *HER2* gene amplification or protein overexpression has traditionally been considered a poor prognostic factor. However, in a recent retrospective analysis, patients with *HER2*-positive metastatic breast cancer treated with first-line trastuzumab had improved 1-year survival rates compared to patients with *HER2*-negative metastatic breast cancer or patients with *HER2*-positive metastatic breast cancer who did not receive trastuzumab.[66] These results demonstrate the powerful impact trastuzumab therapy has made on improving patient outcomes. The outcomes of patients with *HER2*-positive breast cancer may continue to change with the advent of new targeted therapies being used in the treatment of all stages of breast cancer.

Although there is a growing understanding of the prognostic significance of individual factors, it is not clear how each contributes to the overall prognosis for an individual patient. Computer-aided models, including Adjuvant! (*www.adjuvantonline.com*) are available that combine patient- and tumor-related variables to estimate overall prognosis for individual patients with early stage breast cancer and aid in decisions regarding adjuvant systemic therapy.[67] Such programs have limitations, and should be used by healthcare professionals and not directly by patients because of the importance of accurate data entry, selection of different treatment options, and appropriate interpretation of results (see Systemic Adjuvant Therapy below).

Genetic profiling is also being used to provide prognostic and predictive information on clinical outcomes of breast cancer. The Oncotype DX assay uses a reverse-transcription polymerase chain reaction assay of 21 genes to predict the likelihood of distant recurrence in lymph node-negative and ER-positive breast cancer patients treated with tamoxifen.[68] A recurrence score is calculated to categorize patients into low-, intermediate-, or high-risk groups. MammaPrint is another molecular prognostic test that uses DNA microarray analysis to measure the activity of a set of 70 genes to determine the likelihood of breast cancer recurrence in women with stage I or II breast cancer, tumor size 5 cm or less, and no lymph node involvement. To predict the risk of breast cancer metastasis, an algorithm is used to issue a score that indicates whether the patient is at low or high risk.[69] These tools provide additional prognostic information to aid in decision making regarding treatment for these subgroups of patients with otherwise favorable prognostic features. Prospective validation of these assays is required, and clinical trials such as TAILORx and MINDACT are ongoing. Genetic profiling is also being studied for predicting responsiveness or resistance to treatment, and has immense potential for improving prognostic and predictive accuracy.

Novel molecular markers that have shown prognostic and predictive significance include urokinase-type plasminogen activator and its inhibitor, plasminogen activator inhibitor type 1, cyclin E, and presence of tumor cells in bone marrow and/or circulating blood.[70] Completion of prospective validation studies will provide further information as to whether these tests are suitable for use in making treatment decisions in individual patients.

In summary, lymph node status and tumor size are two significant prognostic factors that assist clinicians in estimating prognosis and making treatment recommendations for most breast cancer patients (see also Systemic Adjuvant Therapy below). Although the risk of recurrence is clearly high in patients with large primary tumors or lymph node-positive disease, many patients with small primary tumors and lymph node-negative disease will still develop metastases, yet our ability to accurately identify these individual patients is limited. Evaluation of additional prognostic factors can help identify which patients will have a good outcome with local therapy alone, as well as those patients with aggressive features who would benefit from more aggressive, multimodality treatment.

TREATMENT

EARLY BREAST CANCER (STAGE I AND II)

Local–Regional Therapy

2 Most patients presenting with breast cancer today have either an in situ tumor, a small invasive tumor with negative lymph nodes (stage I), or a small invasive tumor with axillary lymph node involvement (stage II). Surgery alone can cure most, if not all, patients with in situ cancers, 70% to 80% of patients with stage I, and about one half of all patients with stage II cancers. The choice of surgical procedures has changed drastically over the past 50 years. This is partly a result of changes in our understanding of the biology of breast cancer, and is partly a result of a series of well-conducted clinical trials performed over this time period.

The Halstedian theory and concept of tumor growth, formulated at the end of the 19th century, held that breast cancer was a local–regional disease that spread to involve larger contiguous areas of the breast, chest wall, and adjacent lymph nodes. This hypothesis gave rise to the Halsted radical mastectomy, a surgical approach based on the rationale that cure of early disease could best be achieved with expansive, meticulously performed surgical procedures. *Radical mastectomy* involves removal of the breast and both major and minor pectoralis muscles. The axillary nodes on the same side (ipsilateral) as the breast lesion are also removed. Substantial morbidity is associated with this procedure. Muscle resection decreases strength and range of motion, and removal of axillary lymph nodes can produce edema of the arm and resected breast area. This procedure was often followed by external beam radiation therapy to the involved area.

During the 1960s, it was recognized that breast cancer is often microscopically disseminated at the time of initial diagnosis. This evolutionary concept that breast cancer is not only a local, but also a systemic disease, resulted in major changes in local and systemic therapy. The modified radical mastectomy, also termed *total mastectomy with axillary lymph node dissection*, became the standard surgical approach in the 1970s and was not as precisely defined or standardized as the radical mastectomy. The pectoralis minor muscle may be excised, divided, or left intact, and more importantly, there may be variation in the extent of axillary lymph node dissection, ranging from sampling to full dissection (including levels I and II ipsilateral axillary lymph nodes). Despite the lack of standardization, the modified radical mastectomy procedure is associated with significantly less morbidity and long-term complications compared to its radical counterpart.

Results of several large trials have since repudiated the Halsted theory and supported the alternative systemic hypothesis. Over the years these trials have investigated reducing the amount of surgery required to maintain acceptable cosmetic results and rates of local and distant recurrence and mortality. Breast-conserving therapy (BCT) includes removal of part of the breast, surgical evaluation of the axillary lymph node basin, and radiation therapy to the breast. The amount of breast tissue removed as a part of BCT varies

from just removing the cancerous "lump" (a lumpectomy) with a small margin of adjacent normal-appearing tissue, to removing the "lump" with a wider excision of adjacent normal-appearing tissue (a wide local excision), to removing the entire quadrant of the breast that includes the cancerous "lump" (a quadrantectomy). All of these techniques are referred to as a *segmental or partial mastectomy*. In 1990, the National Institutes of Health Consensus Development Conference reviewed six trials comparing modified radical mastectomy with BCT.[71] Those patients who underwent BCT had removal of only part of the breast, and an axillary lymph node dissection followed by radiation therapy to the whole breast. From this analysis, the National Institutes of Health conference concluded that "BCT is an appropriate method of primary therapy for the majority of women with stage I and stage II breast cancer and is preferable because it provides survival equivalent to total mastectomy and axillary dissection while preserving the breast."[71] The median follow-up for these trials was 6.5 years at the time the National Institutes of Health conference was convened and this recommendation was made.

In a meta-analysis of updated information from these same six trials with a median follow-up of 14.7 years, the authors concluded that no difference in overall survival between mastectomy and BCT remained.[72] However, with longer follow-up it does appear that local recurrence rates are significantly higher with BCT (pooled data odds ratio [OR], 1.56; 95% CI, 1.29-1.89; P <0.001). This observation was also demonstrated in previous meta-analyses, including one by Morris et al. reported in 1997,[73] the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) overview completed in 2000, [74] and one by Yang et al. reported in 2008.[75] Although local–regional recurrences are concerning, it is not clear what impact they have on overall survival. In the Jatoi meta-analysis, no impact on overall survival was seen with more than 4,000 patients included in the analysis.[72] But in the EBCTCG meta-analysis, which included 25,000 women, increased locoregional recurrences were associated with increased breast cancer mortality.[74] Collectively, these data indicate that any negative impact on survival, if present, is probably very small, and competing causes of death from adverse effects related to cancer therapy and comorbid diseases must be considered to determine the overall risks associated with BCT for an individual patient. These risks should be weighed against the potential benefits of any local therapy. Also, most patients with early stage breast cancer receive systemic adjuvant therapy (to be discussed later; see Systemic Adjuvant Therapy below), which further reduces the risk of recurrence and death from breast cancer, possibly negating any potential increase in recurrence attributed to BCT. Because the studies included in all of these meta-analyses are quite heterogeneous and of varying quality, it is difficult to draw sound conclusions. Other clinical trials have investigated methods to better identify patients at high risk for recurrence to better define who might be appropriate candidates for BCT compared with mastectomy. Some clinical trials suggest that young age (<35 years) is predictive for ipsilateral breast recurrences, but these trials also indicate a similar survival with BCT compared with mastectomy in this same population.[76,77] Women with a family history of breast cancer or an identified mutation in *BRCA1* or *BRCA2* are more likely to exist in this younger population, which may confound the independent contribution of age and treatment on clinical outcome.[78] This may be a result of the high risk of another cancer developing in the remaining breast tissue rather than a recurrence of the previously diagnosed cancer. However, despite the lack of sound clinical evidence to support the recommendation, the National Comprehensive Cancer Network (NCCN) recommends that women who are 35 years of age or younger, or who are premenopausal and a carrier of a known *BRCA1* or *BRCA2* mutation, undergo mastectomy and consider additional risk reduction strategies (e.g., bilateral mastectomies).[47] Bilateral total mastectomy and/or oophorectomy reduce the risk of breast cancer occurrence in patients with *BRCA1* or *BRCA2* mutations, but both breast and ovarian cancers have been reported in patients who have had prophylactic removal of these organs. Most experts agree that BCT is an appropriate option for local therapy of early stage breast cancer. BCT is appropriate for most women, but full disclosure of the risks and benefits should be made and thoroughly discussed, and the patient's clinical situation and preferences should be carefully considered prior to undergoing any such procedure.

Most patients diagnosed today with breast cancer can be treated with BCT. Several factors should be considered in selecting patients for BCT. Multiple sites of cancer within the breast and the inability to attain negative pathologic margins on the excised breast specimen are predictive for an increased risk of recurrence with BCT and are indications for mastectomy. Some preexisting collagen vascular diseases (e.g., scleroderma and systemic lupus erythematosus) are relative contraindications for the use of BCT because of an increased risk of radiation-related adverse effects. Although local recurrence following BCT has not been consistently associated with increased mortality, it is distressing to the patient and requires surgical removal of the breast. In addition, reconstructive therapy is often not feasible in a breast that has previously received irradiation. Another major consideration in selecting patients for BCT is the expected cosmetic result. Although tumor size is not an important consideration for breast cancer recurrence if negative margins can be achieved, the relationship of the size of the tumor to the total breast volume is an important cosmetic consideration. If the volume of the tissue removed encompasses a significant portion of the breast, better results may be obtained with mastectomy and reconstruction. Additionally, for some patients, preservation of a limited amount of breast tissue may not justify the inconvenience of radiation therapy. Another approach to therapy for these patients is primary (neoadjuvant) systemic therapy to potentially shrink the tumor and minimize surgery (see sections on Systemic Adjuvant Therapy and Locally Advanced Breast Cancer for further details). Aside from the probability of local recurrence and the ability to achieve a satisfactory cosmetic result, consideration must be given to the availability of an external beam radiation facility and the patient's willingness to comply with the prescribed course of radiotherapy. In most instances, external beam radiation therapy used in conjunction with breast-conserving procedures involves 4 to 6 weeks of radiation therapy directed to the entire breast tissue (typically a total of 50 Gy [5000 Rad] administered in 25 daily doses Mondays through Fridays, with an optional boost of radiation) to eradicate residual disease. Complications associated with radiation therapy to the breast are minor and include reddening and erythema of the breast tissue and subsequent shrinkage of total breast mass beyond that predicted on the basis of breast tissue removal.

Although the current standard of care is to include local radiation therapy to the whole breast as a required component of BCT, current clinical trials are investigating the use of accelerated partial breast irradiation, intraoperative radiotherapy, or no radiation after segmental mastectomy for certain patient populations with a very low risk of recurrence.[79] Potential advantages of partial breast irradiation include decreased volume of breast tissue irradiated and shorter duration of treatment. Partial breast irradiation can be delivered with brachytherapy (such as with the Mammosite device) or external beam irradiation (with 3-D conformational radiation or intensity modulated radiation therapy). Others are investigating a single dose of radiation intraoperatively. None of these newer methods are considered standard of care, but may be included as part of a clinical trial. The underlying goal of local therapy is to minimize complications while maximizing outcomes that are

relevant to the patient (e.g., cosmetic results, local and distant recurrence rates, mortality).

Postmastectomy radiation therapy to the chest wall may also be required in certain situations where tumors are large or the number of positive axillary lymph nodes is high (see section on Locally Advanced Breast Cancer). However, these criteria are also widely debated and are the subject of several meta-analyses. Despite the controversy, it is clear that some women may benefit from local radiation therapy even after removal of the entire breast (i.e., total mastectomy). The NCCN Guidelines state that women with the following criteria should undergo postmastectomy radiation therapy: (a) positive surgical margins, (b) a tumor larger than 5 cm in greatest dimension, or (c) four or more positive axillary lymph nodes.[47] Patients with close margins (<1 mm of normal adjacent tissue) or one to three positive ipsilateral axillary lymph nodes should consider postmastectomy chest wall radiation therapy, but the benefits are controversial. Patients with surgical margins of at least 1 mm, tumor size of 5 cm or less and negative axillary lymph nodes do not require postmastectomy chest wall radiation therapy. The optimal sequence of radiation therapy and chemotherapy is somewhat controversial. Concurrent administration of chemotherapy and radiation therapy is usually avoided because of an increase in local adverse effects. Most clinicians administer systemic chemotherapy immediately following surgery (if chemotherapy was not administered prior to surgery) given the hypothetical presence of systemic micrometastases that cannot be eradicated by local radiation therapy. Radiation therapy is then administered after chemotherapy, leaving hormone therapy (which is given for many years) for the end (see section on Adjuvant Biologic Therapy for discussion of sequencing trastuzumab).

Accurate assessment of the spread of breast cancer cells to the axillary lymph nodes is critical for prognosis and the determination of the utility of both local and systemic treatments. Axillary lymph node dissection with histopathologic study of the full axillary specimen, including level I and II lymph nodes, was the gold standard for detecting axillary nodal involvement and determining the number of lymph nodes containing tumor. The number of positive axillary lymph nodes remains the most powerful predictor of breast cancer recurrence and survival, but other benefits may include a therapeutic effect of removing the lymph nodes and obtaining information to guide treatment selection. However, axillary dissection is associated with significant morbidity, with an acute complication rate as high as 20% to 30% and rates of chronic lymphedema as high as 20% to 30%.[80,81] Recent studies indicate that approximately 60% of patients with early stage breast cancer present with lymph node-negative disease, which indicates that many women would derive no therapeutic benefit, but would be exposed to the complications from the procedure.

For these reasons, a procedure involving lymphatic mapping and sentinel lymph node biopsy (SLNB) is increasingly accepted at many centers across the United States and guidelines regarding recommendations for this procedure are now available.[82–84] The sentinel lymph node(s) is the first lymph node(s) that receives lymph drainage from the primary tumor. Injection of a vital blue dye, a radiocolloid, or both around the primary breast tumor identifies the sentinel lymph node(s) in most patients, and the status of this lymph node(s) may predict the status of the remaining nodes in the nodal basin. Patients with lymph nodes that are suspicious for cancer involvement either by physical exam or imaging should have a biopsy performed to exclude lymph node involvement. SLNB has become the standard of care for patients with clinically negative axillary lymph nodes.[47,85] Patients with a positive sentinel node or in cases where the sentinel node is not identified should proceed to a level I and II axillary lymph node dissection, although the definition of sentinel lymph node positivity is also controversial.

Many uncontrolled studies support the use of sentinel lymph node biopsy. Despite differences in the mapping technique, the experience of the surgeon, or the patient populations studied, recent studies show that the technique identified the sentinel lymph node(s) in more than 90% of patients.[84] In studies that incorporated completed axillary dissections for comparison, the SLNB procedure accurately predicted the status of the remaining axillary nodes in more than 90% of patients. Considerable controversy exists over the use of this procedure in women with large tumors (>5 cm) or locally advanced disease, palpable axillary lymph nodes, a multifocal or multicentric breast tumor, prior neoadjuvant (preoperative) chemotherapy, or prior surgery involving the breast and/or axilla. Patients who are pregnant or lactating are generally not considered candidates for this procedure due to concerns regarding the effects of the blue dye and/or the radiocolloid on the fetus.

Another factor that should be considered is the experience and mastery of the procedure by the surgical team. It has been shown that an individual surgeon must perform at least 20 procedures to attain competency, and the American Society of Breast Surgeons has incorporated this caveat into its *2005 Consensus Statement on Guidelines for Performing Sentinel Lymph Node Dissection for Breast Cancer*.[86] The false-negative rate with this procedure appears to inversely correlate with the rate of identification of the sentinel lymph node and may also be an early indicator of accuracy within an institution.[84]

The long-term outcome of patients who are undergoing this procedure alone (without axillary dissection) is unknown. Ongoing clinical trials will hopefully provide answers to these questions. A recent meta-analysis of 48 studies involving nearly 15,000 patients with a clinically negative axilla and a SLNB (without subsequent ALND) showed a median weighted axillary recurrence rate of 0.3% and a median weighted sensitivity for SLNB to detect axillary cancer cells of 100% (range, 97%–100%).[87] These results are reassuring, albeit with a relatively short median follow-up of less than 3 years. Despite the absence of long-term data, total mastectomy with SLNB (without ALND) can spare patients from the morbidities associated with an axillary lymph node dissection while providing critical information about breast cancer prognosis to guide local and systemic treatment decisions. The decision of whether to use the sentinel lymph node procedure or a full axillary dissection is complex and the reader is referred to excellent reviews and guidelines for further information.[82–84,86]

Simple or *total mastectomy* involves removal of the entire breast without dissection of the underlying muscle or axillary nodes. The major disadvantage of this procedure is that axillary nodal status is not determined, and therefore important prognostic information may be lost. This procedure is used in patients with carcinoma in situ, in whom there is a 1% incidence of axillary node involvement, or in cases of in-breast recurrences following BCT.

The early trials investigating less-extensive surgical approaches to breast cancer are widely credited with the finding that BCT is an appropriate primary therapy for most women with stages I and II disease, and is preferable because it arguably provides survival rates equivalent to those of modified radical mastectomy. But these trials provided valuable information regarding the natural history of the disease and identified pathologic prognostic factors associated with early cancer spread. The preponderance of information available regarding selection of women most likely to benefit from systemic adjuvant therapy was derived from pathologic evaluation of tissues archived from these early trials. It is hoped that further investigation into less-extensive local therapy (now focused on the surgical approach to the axilla and radiation therapy) will continue to provide valuable information for the future.

TABLE 136-6 Laboratory Findings, Clinical Observations, and Biologic Hypothesis of Breast Cancer as a Systemic Disease and the Value of Adjuvant Chemotherapy

- By the time cancer becomes clinically detectable, it is advanced (about 30 doublings) and has had ample opportunity to establish distant micrometastases.
- There is no orderly pattern of tumor cell dissemination, and the bloodstream is of considerable importance in tumor spread.
- Operable breast cancer is often a systemic disease and variations in local–regional therapy have not substantially affected survival. Only by control of distant disease can there be an improvement in the outcome of breast cancer patients.
- Likelihood of disease recurrence is related to size of tumor mass and axillary node involvement at diagnosis.
- Recurrence of breast cancer following local–regional therapy is most commonly at sites distant from the breast.
- Tumor growth fraction is inversely related to tumor population. Therefore, optimal kinetic conditions to achieve cure with chemotherapy exist in the setting of micrometastatic disease.
- Efficacy of chemotherapy is dose dependent and optimal doses of combination chemotherapy can be more safely and effectively administered in the adjuvant setting as opposed to the setting of advanced disease.

Systemic Adjuvant Therapy

3 *Systemic adjuvant therapy* is defined as the administration of systemic therapy following definitive local therapy (surgery, radiation, or a combination of these) when there is no evidence of metastatic disease, but a high likelihood of disease recurrence. The concept of breast cancer being a systemic disease and the rationale of adjuvant chemotherapy was based on a series of laboratory and clinical investigations conducted during the 1960s and 1970s that were directed primarily toward achieving a better understanding of tumor metastases. Table 136–6 illustrates the laboratory findings, clinical abnormalities, and biologic hypotheses that lead to recognition of breast cancer as a systemic disease and documented the value of adjuvant chemotherapy. The earliest adjuvant trials in breast cancer consisted of perioperative administration of alkylating agents with the intent of eradicating micrometastases that were disseminated at the time of surgical excision of the tumor. Many collaborative research groups have conducted stepwise series of studies designed to identify appropriate candidates for systemic adjuvant therapy, and the optimal regimens and duration of therapy. Several hundred randomized clinical trials evaluating various systemic adjuvant modalities have been reported. Most published results confirm that chemotherapy, hormonal therapy, or both, result in improved disease-free survival (DFS) and/or overall survival (OS) for all treated patients, or more commonly for patients in specific prognostic subgroups (e.g., nodal involvement, menopausal status, hormonal receptor status, or *HER2* status). The huge amounts of data generated by these trials have resulted in a great deal of controversy, with different conclusions being reached by various experts.

Interpretation of results of systemic adjuvant therapy is difficult because of differences in the patient populations studied, the variation in natural history of breast cancer, the absence of information regarding pathologic prognostic factors in many studies, and differences in treatment approach and methods of analysis. It is important to remember that because the goal of systemic adjuvant therapy is cure, patients in these studies must be followed for long periods of time before results can be determined. In addition, because most patients with early breast cancer (50%–90%) in the various trials are cured with local–regional therapy alone, large numbers of patients are required to show a statistically significant difference that can be attributed to systemic adjuvant therapy. For these reasons, several groups around the world have conducted meta-analyses of similar breast cancer trials in hopes of gaining more insight regarding adjuvant systemic therapy than a single study can provide. One such effort, organized by the EBCTCG, is based on a worldwide collaboration involving multiple randomized trials and is continually updated with results from new clinical trials.[5] The EBCTCG overview analyses are updated every 5 years and have been published in 1988, 1992, 1998, and 2005. The most recent update, published in 2005 as a result of analyses that took place in 2000, reflects the 10-year and 15-year effects on breast cancer recurrence and survival, respectively. Many important questions regarding the optimal way to administer adjuvant chemotherapy and hormonal therapy, and the magnitude of benefit as measured by DFS or OS to clinically relevant subsets of patients, have been answered by these overview analyses. Simply stated, the results of these analyses support the use of adjuvant hormonal therapy in all patients with positive hormone receptor status, regardless of age, menopausal status, involvement of axillary lymph nodes, or tumor size. The results of these overview analyses also support the use of adjuvant chemotherapy in most women with lymph node metastases or with primary breast cancers larger than 1 cm in diameter (both node-negative and node-positive).[5] It is important to note that data from clinical trials incorporating the taxanes, modern aromatase inhibitors, or trastuzumab into adjuvant chemotherapy regimens were not included in these analyses, as trials with these agents were not started by 1995, the cut-off for data inclusion.[5] Results from these more recent clinical trials are discussed later (see sections on Adjuvant Chemotherapy, Adjuvant Biologic Therapy, and Adjuvant Endocrine Therapy).

It is important to understand the relative and absolute magnitude of benefit associated with adjuvant systemic therapy in breast cancer. Table 136–7 shows the proportional reduction in the annual odds of recurrence and death by age for adjuvant polychemotherapy and adjuvant tamoxifen given for 5 years in women with tumors that are positive for hormone receptors based on the results of these overview analyses. Throughout these reports, the results are presented as they are in Table 136–7, as proportional benefits that compare the effects of two groups, in this case, chemotherapy or hormonal therapy versus no chemotherapy or hormonal therapy. A proportional reduction of 25% might equivalently be described as an OR, RR, or HR of 0.75; a RR or odds reduction of 25%; or a 25% reduction in the risk of death or death rate. For a given proportional reduction in death rate, the absolute improvement in 15-year survival will depend on the baseline risk of death with no treatment, which varies based on prognostic factors that include patient characteristics, disease characteristics and biomarkers identified earlier in this chapter. Table 136–8 shows the number of deaths avoided per 100 patients treated in several hypothetical subsets of patients with different estimated 15-year survivals without adjuvant therapy,

TABLE 136-7 Fifteen-Year Results of the Overview Analysis

	Tamoxifen vs None[a] Reduction in Annual Odds		Polychemotherapy vs None Reduction in Annual Odds	
Age (years)	***Recurrence (%)***	***Death (%)***	***Recurrence (%)***	***Death (%)***
All patients	39 ± 3	32 ± 4	23 ± 2	17 ± 2
<40	44 ± 10	39 ± 12	40 ± 6	29 ± 7
40–49	29 ± 7	24 ± 9	36 ± 4	30 ± 5

as a function of different estimates of treatment benefit shown as the proportional reductions in mortality if they did receive adjuvant therapy. About 15 of every 100 patients benefited at 15 years from adjuvant therapy when a 30% proportional reduction in mortality is observed in the highest-risk subgroups (50% death rate with no adjuvant therapy). In contrast, the same 30% proportional reduction in mortality translated into a benefit for only 3 of 100 patients in the lowest-risk subset (10% death rate with no adjuvant therapy). Thus the absolute benefit of adjuvant therapy depends on both the proportional reduction in mortality and the risk of disease recurrence, with the greatest benefit observed in the highest-risk treatment groups. Table 136–9 uses data from the overview analyses to show the absolute benefits of adjuvant chemotherapy in terms of age and nodal status. In the highest-risk group, node-positive women younger than 50 years of age, only 42.8% were alive at 10 years with no polychemotherapy as compared to 54.2% with polychemotherapy, which translates into an absolute survival benefit of 11.4%. However, in the node-negative group, patients younger than 50 years old where survival with no polychemotherapy was highest (i.e., 76.3%), the addition of polychemotherapy produced an absolute benefit of only 4.8%. It should be pointed out that all of these differences in survival are clearly statistically significant and form the basis for national and international guidelines that recommend offering cytotoxic chemotherapy to most women with early stage breast cancer.[47,88] However, the absolute benefit in node-positive women 50 to 69 years old is quite small (2.7%), and depending on other disease characteristics and comorbid conditions, patients may elect not to pursue treatment. Although a 2% absolute reduction in death attributable to polychemotherapy may appear small, at least two investigators report that most patients with breast cancer would accept severe toxicity from treatment to achieve as little as a 1% to 5% absolute improvement in survival.[89,90]

Several international and national groups have developed guidelines for treatment of early stage breast cancer based on specific patient and disease characteristics and the results of the overview analyses. The two most commonly referenced guidelines are the St. Gallen International Expert Consensus Conference and the NCCN guidelines.[47,88] The St. Gallen guidelines are updated every 2 years by an international group of researchers that meet in St. Gallen, Switzerland to review available evidence and create consensus recommendations for selection of adjuvant systemic therapies in specific patient populations outside of the framework of clinical trials. The NCCN has also developed practice guidelines for the treatment of breast cancer which are updated annually or more often based on the available evidence. Recommendations from the NCCN for patients with tumors 1 cm or larger or positive lymph nodes are summarized in Figure 136–5. For patients with tumors less than 1 cm, micrometastatic lymph node involvement, or negative lymph nodes, treatment is highly individualized and based on multiple patient- and tumor-related factors, including hormone receptor status, *HER2* status, concomitant comorbidities, and patient preference. Specific treatment recommendations are complex and the reader is referred to the guideline for further details.

Intensive research efforts are directed toward identifying those characteristics of the primary tumor (e.g., pathologic or molecular prognostic factors) that may predict for a higher or lower likelihood of distant metastases and death in node-negative patients. Although many prognostic factors are being investigated, no single factor or combination of factors sufficiently identifies those at risk of metastases or is sufficiently standardized to be reproducibly applicable to all patients. Currently, two commercially available genetic tests are being prospectively validated as decision-support tools for adjuvant chemotherapy. Oncotype DX is one of these tests which screens for expression of 21 genes using reverse-transcription polymerase chain reaction and results in a recurrence score that can be used to determine the risk of distant recurrence and/or death from breast

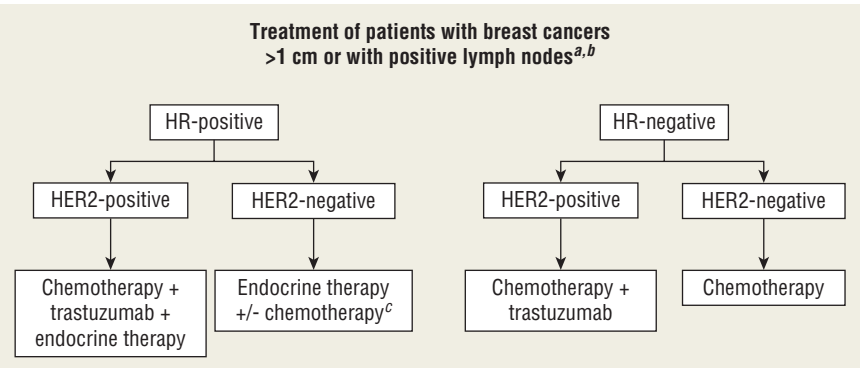

FIGURE 136-5. Treatment of patients with breast cancers >1 cm or with positive lymph nodes. HR, hormone receptor; HER2, human epidermal growth factor receptor-2. [a]Refer to text for definitions of HR and HER2 positivity. [b]Refer to text for management of patients with tumors <1 cm, micrometastatic lymph node involvement, or negative lymph nodes. [c]Oncotype DX may identify patients who derive little benefit from chemotherapy (lymph node negative patients only) (see Systemic Adjuvant Therapy section for details).

cancer in women with ER-positive, node-negative, invasive breast cancer.[68] The tumor tissue used for this test is paraffin-embedded tumor from archived samples. A low recurrence score (<18) indicates a low risk of recurrence with endocrine therapy alone indicating that perhaps adjuvant chemotherapy could be avoided. A high recurrence score (≥31) would indicate a high risk of recurrence despite endocrine therapy, suggesting a need for adjuvant chemotherapy followed by endocrine therapy. The utility of chemotherapy in patients with an intermediate score (18–30) is unclear, and ongoing clinical trials hope to further elucidate the role of Oncotype DX in this patient population. A second test, MammaPrint, was approved to estimate prognosis in breast cancer patients with early-stage disease, regardless of hormone receptor status. MammaPrint screens the tumor for 70 genes using microarray technology. The assay requires fresh-frozen tissue and reports the predicted rates of recurrence as high or low. This information has been shown to accurately predict for recurrence in a subset of patients not receiving systemic adjuvant therapy.[69] The MINDACT (Microarray In Node-negative Disease may Avoid ChemoTherapy) trial, ongoing in Europe, will compare the predictive capabilities of MammaPrint against the standard prognostic factors to assess which patients with node-negative, ER-positive breast cancer will benefit from adjuvant chemotherapy. We await further information to guide the use of these novel pharmacogenomic tools.

A clinical tool that is gaining favor is an Internet-based tool called Adjuvant! (*www.adjuvantonline.com*), which helps clinicians and patients make informed decisions regarding adjuvant therapy for breast, colon, and lung cancers. The tool allows healthcare professionals to estimate the risks of negative outcomes (e.g., cancer recurrence and/or death), and the potential benefits of therapy (e.g., reductions in risks of recurrence and/or death). This is a validated, evidence-based tool which incorporates multiple prognostic and predictive factors into a mathematical model in which each factor is weighted based on established evidence from clinical trials and is placed in the background of the Surveillance, Epidemiology, and End Results (SEER) database for patients living in the United States.[91,92] By entering the patient's age, comorbidities, ER status, tumor grade, tumor size, and nodal status, the clinician can use the tool to estimate the breast cancer mortality and/or recurrence risk at 10 years and determine the impact of chemotherapy, hormone therapy or both on these risks. The results are then projected in a graphic format which is easy to understand and explain to patients. Some of the limitations of Adjuvant! include the limited information regarding outcome in patients with tumors that are smaller than 1 cm and no axillary lymph node involvement; it does not incorporate proliferation markers or *HER2* status of the primary tumor; and it does not consider potential adverse effects of therapy. Estimates of outcome with the Adjuvant! program may also vary in specific subgroups of patients, such as women who are diagnosed with breast cancer at a younger age. For a more in-depth discussion of the issues and controversies regarding adjuvant therapy of breast cancer, the reader is referred to two excellent reviews.[93,94]

The use of preoperative systemic therapy is gaining favor in both early stage and locally advanced breast cancers. This approach to therapy, referred to as *neoadjuvant* or *primary systemic therapy*, usually consists of chemotherapy, but in special circumstances may also include hormonal therapy (e.g., in inoperable patients with significant comorbidities). Advantages of preoperative systemic therapy include (a) a decrease in the size of the tumor to minimize surgery; (b) determining the response to chemotherapy/hormone therapy in vivo (an important prognostic indicator); and (c) other theoretical advantages (e.g., delivery of chemotherapy through an intact vascular system). In a pivotal study conducted by the NSABP (Trial B18), preoperative chemotherapy was compared to traditional chemotherapy given after surgery (same chemotherapy and same number of cycles).[95,96] Although no difference was found in DFS or OS, rates of BCT were higher in the group receiving preoperative chemotherapy (67.8% vs 59.8%).[96] This study also identified a small subset of patients (13%) who had a pathologic complete response (no tumor left at surgery) after chemotherapy. These patients went on to have a significantly longer DFS as compared with patients who did not achieve a pathologic complete response (P <0.0001).[96] Importantly, even after 16 years of follow-up, patients who achieved a pCR continued to have superior DFS and OS compared with patients who did not achieve a pCR.[97] While this approach to therapy was historically reserved for patients with inoperable tumors (locally advanced), the use of preoperative systemic therapy in patients with early-stage breast cancer is increasing in popularity due to the ability to assess the response to therapy in vivo as well as the potential to decrease the size of the tumor, allowing for less radical surgery and better cosmetic results.

4 Adjuvant Chemotherapy Cytotoxic drugs that have been used alone and in combination as adjuvant therapy in breast cancer include doxorubicin, epirubicin, cyclophosphamide, methotrexate, fluorouracil, paclitaxel, docetaxel, melphalan, prednisone, vinorelbine, and vincristine. Table 136–10 lists some of the most common combination chemotherapy regimens employed in the adjuvant setting.

The basic principle of adjuvant therapy for any cancer type is that the regimen with the highest response rate in advanced disease should be the optimal regimen for use in the adjuvant setting. However, results from individual clinical trials investigating specific regimens in the adjuvant setting are required to identify the benefits and risks in a specific patient population. Early administration of effective combination chemotherapy at a time when the tumor burden is low should increase the likelihood of cure and minimize the emergence of drug-resistant tumor cell clones. Historically, combination chemotherapy regimens (polychemotherapy) have been more effective than single-agent chemotherapy. Anthracyclines (doxorubicin and epirubicin) and more recently taxanes (paclitaxel and docetaxel) have become the cornerstones of modern chemotherapy for the adjuvant treatment of breast cancer. The overview analysis of polychemotherapy (discussed previously) analyzed results from 17 trials that directly compared an anthracycline-containing regimen with a cyclophosphamide, methotrexate, fluorouracil (CMF)-type regimen and demonstrated a significant advantage with the anthracycline regimens.[5] In that meta-analysis, anthracycline-containing regimens were modestly superior in reducing recurrence and death as compared to regimens without anthracyclines. An 11% ± 3% reduction in annual odds of recurrence and a 15% ± 3% reduction in annual odds of death were reported in the 2005 update, which translated into an absolute difference in OS of 3% at 5 years and 4% at 10 years.[5] None of the clinical trials included in this meta-analysis contained a taxane.

Because the taxanes are relatively new, adjuvant studies including them have not yet been incorporated into the published EBCTCG overview analyses. However, in a pooled analysis of 22,903 patients from 13 trials, the addition of a taxane resulted in significant increases in DFS and OS (HR, 0.83; 95% CI, 0.79-0.87; P <0.00001; HR, 0.85; 95% CI, 0.79-0.91; P <0.00001; respectively).[98] Importantly, these trials included both sequential and concurrent taxane therapy (paclitaxel or docetaxel) in conjunction with anthracyclines (with or without cyclophosphamide, fluorouracil, and/or methotrexate). Regardless of administration (e.g., weekly, every 3 weeks, prolonged or short infusions) or type of taxane, DFS and OS were consistently and significantly improved. Most of these trials enrolled node-positive patients only, but some also included high-risk node-negative patients. Taxane-containing,

[n] Another way to give these agents in a dose-dense manner is A → P → C as sequential single agents, in the same doses indicated above, every 14 days for 4 cycles each with growth factor support.

non-anthracycline regimens may be appropriate for some patients with a low risk of disease recurrence. However, this subject remains widely debated.

CLINICAL CONTROVERSY

Although incorporation of taxanes into many different adjuvant chemotherapy regimens, both sequentially and concurrently, has led to a shift in therapy for node-positive breast cancer patients, the use of taxane-containing regimens in node-negative patients remains controversial. The use of an anthracycline-containing regimen is established for both node-negative and node-positive breast cancer patients.

There is no apparent biologic reason why node-negative disease should respond differently to the taxanes than node-positive disease. However, the absolute benefits for this population may not be large enough to warrant a change from the standard of care. Further follow-up from these trials will continue to address this issue. Since the addition of a taxane may predispose patients to some transient peripheral neuropathy, myelosuppression, and alopecia, adverse events should also be considered. The long-term adverse events related to these regimens are yet to be determined. Also, the cost-effectiveness of adding a taxane to an adjuvant regimen is still largely debated given the paucity of reliable information addressing this issue.

Cytotoxic chemotherapy is a particularly important treatment modality for patients with tumors that do not express ER or PR and do not overexpress *HER2* (so called triple-negative breast cancers, TNBC). Patients with TNBC treated with anthracycline and taxane-based chemotherapy have significantly decreased survival compared to patients with other breast cancer subtypes. Ironically, this subgroup of patients is more likely to respond to neoadjuvant chemotherapy. Therefore, patients with TNBC who achieve a pCR have an excellent long-term survival, but those who have residual disease at the time of surgery have a worse prognosis than non-TNBC patients.[99] The optimal type and duration of chemotherapy for patients with TNBC is unknown. Because none of the previously identified molecular targets are present in TNBC, incorporation of non-traditional chemotherapy (e.g., platinum agents) into these regimens is under investigation. Identification of meaningful molecular targets is much needed and is where most research is ongoing. Molecular targets of interest include epidermal growth factor receptor (EGFR), vascular endothelial growth factor (VEGF), and poly-ADP ribose polymerase (PARP).

No validated predictive factors exist for response to chemotherapy, but some studies suggest that *HER2* status and ER negativity may be useful predictors of response. Some retrospective studies suggest that the benefit of anthracycline-containing regimens over CMF-like regimens is limited to those tumors that overexpress *HER2* or are topoisomerase II (*TOP2A*) amplified. This concept is theoretically plausible, since *HER2* and *TOP2A* are closely located on chromosome 17 and *TOP2A* is a known target for anthracycline therapy. However, data supporting these relationships are contradictory, and therefore should not influence chemotherapy treatment decisions at this time. ER status has also been evaluated as a predictor of response to chemotherapy. Several clinical trials have attempted to correlate ER-negative status with response to adjuvant chemotherapy, but the results of these studies are inconsistent and decisions concerning chemotherapy should not be based on ER status at this time. Several investigators have attempted to predict response to specific chemotherapy regimens (e.g., taxane-containing regimens) with microarray technology, which uses DNA from the tumor to test for thousands of genetic mutations. Although these types of genetic tests need to be validated in prospective clinical trials, they may serve in the future to help determine what chemotherapy regimen a patient should receive to gain the most

benefit. For the time being, chemotherapy options are chosen based on the prescriber's experience with the regimen and current evidence from clinical trials.

Although the optimal duration of adjuvant chemotherapy administration is unknown, it appears to be on the order of 12 to 24 weeks and depends on the regimen being used. Chemotherapy should be initiated within 12 weeks of surgical removal of the primary tumor.[100] "Dose intensity" and "dose density" appear to be critical factors in achieving optimal outcomes in adjuvant breast cancer therapy. *Dose intensity* is defined as the amount of drug administered per unit of time and is typically reported in milligrams per square meter of body surface area per week (mg/m^2/week). Increasing dose, decreasing time between doses, or both can increase dose intensity. *Dose density* is one way of achieving dose intensity, but not by increasing the amount of drug given, as occurs with dose escalation, but instead by decreasing the time between treatment cycles. The importance of dose intensity first received wide attention in 1981, when the Milan group reported in a retrospective analysis of their original CMF adjuvant study that only those patients who received at least 85% of their planned CMF dose benefited significantly from adjuvant therapy, while those receiving less than 65% of the planned dose had the same DFS and OS as the group of control patients treated with surgery alone.[101] Therefore, dose reductions for standard treatment regimens should be avoided, unless necessitated by severe toxicity. But increasing doses beyond those contained in standard treatment regimens does not appear to be beneficial and may be harmful.

Several studies investigating the impact of *dose density* have now been reported. Interest in this approach to adjuvant therapy was stimulated when the CALGB reported results from their trial 9741 which tested not only dose density, but also the question of using sequential versus combination chemotherapy regimens. Using a 2 × 2 factorial design, investigators randomized node-positive breast cancer patients after surgery to compare sequential versus concurrent chemotherapy, and standard dose versus dose density.[102] The arms of the study were (group 1) sequential doxorubicin (A) for four cycles, followed by paclitaxel (P) for four cycles, followed by cyclophosphamide (C) for four cycles, with all cycles given every 3 weeks; (group 2) sequential A for four cycles, followed by P for four cycles, followed by C for four cycles, with all cycles given every 2 weeks with filgrastim; (group 3) concurrent AC for four cycles, followed by P for four cycles, with all cycles given every 3 weeks; and (group 4) concurrent AC for four cycles, followed by P for four cycles, with all cycles given every 2 weeks with filgrastim. After a median follow-up of 36 months, the patients receiving chemotherapy every 2 weeks had a significantly prolonged DFS (at 3 years: 85% vs 81%; RR, 0.74; $P = 0.01$) and OS (92% vs 90%; RR, 0.69; $P = 0.013$) as compared with every 3-week chemotherapy.[102] The use of sequential versus concurrent chemotherapy did not show a benefit for one over the other in terms of DFS or OS, but sequential therapy did appear to be less toxic. Patients in the concurrent every 2-week group (group 4) had significantly more regimen-related toxicity, including a very high rate of red blood cell transfusions for anemia (13% of cycles).[102] Red blood cell transfusions are rarely required with most other standard adjuvant chemotherapy regimens used for breast cancer.

Dose intensity appears to be important for some drugs but not for others. Many studies with anthracyclines (without taxanes) appear to indicate no benefit from a dose-dense approach to drug administration. These data seem to contradict the CALGB 9741 data. However, data with the taxanes, especially paclitaxel, appear to support a dose-dense (not intense) approach, with weekly therapy producing optimal outcomes.[102] Data with paclitaxel given weekly versus every 3 weeks indicates that this drug is more effective when given weekly in the adjuvant, neoadjuvant, and metastatic settings.[103,104] Thus some speculate that the different paclitaxel schedule is the primary reason for the success with this approach to therapy. A direct comparison between taxane dosing intervals was evaluated in the North American Breast Cancer Intergroup Trial E1199 which randomized patients in a 2 × 2 factorial design to receive doxorubicin and cyclophosphamide for four cycles every 3 weeks followed by either weekly or 3-weekly paclitaxel or docetaxel.[103] While this study does not directly address the question of dose density because of the lower doses given in the weekly arms, it appears to support the pharmacologic advantage of a taxane given more frequently as the essential factor driving the beneficial outcomes seen with "dose density" in the CALGB 9741 trial. Although no differences in DFS or OS were observed between the weekly or 3-weekly schedule or the different taxanes in the E1199 trial, a subgroup analysis indicated that the weekly paclitaxel arm resulted in improved DFS (OR, 1.27; 95% CI, 1.03-1.57; $P = 0.006$) and OS (OR, 1.32; 95% CI, 1.02-1.72; $P = 0.01$) compared to paclitaxel administered every 3 weeks. Docetaxel, when administered every 3 weeks, resulted in improved DFS (OR, 1.23; 95% CI, 1.00-1.52; $P = 0.02$) but not OS (OR, 1.13; 95% CI, 0.88-1.46; $P = 0.25$) when compared to paclitaxel administered every 3 weeks. DFS and OS with weekly docetaxel was not significantly different from paclitaxel administered every 3 weeks. Although other trials have attempted to investigate dose-dense regimens, they also have other variables that were altered that could potentially impact the outcomes. Consequently, they do not directly address the question and their results may be influenced by factors other than dose density. A detailed discussion of these nuances is beyond the scope of this chapter and the reader is referred to excellent references on this topic for further information.[105,106] Nonetheless, despite a relatively short follow-up, unclear overall benefit compared to conventional regimens, and potentially more toxicity, the dose-dense regimens may be considered as options for adjuvant therapy for node-positive breast cancer. Thorough discussion regarding the risks and benefits each individual patient may face is imperative given the uncertainty surrounding these regimens.

A major focus of clinical investigations in the past was the use of high-dose chemotherapy regimens as adjuvant therapy. Because bone marrow suppression is the dose-limiting toxicity for most chemotherapeutic agents, high-dose chemotherapy regimens followed by colony-stimulating factors or reinfusion of autologous hematopoietic stem cells were developed. Several cooperative groups have conducted trials of high-dose chemotherapy with stem cell support versus conventional adjuvant therapy. None of the trials showed a significant difference in DFS or OS. Based on the available evidence, this approach to therapy is currently not recommended outside the context of a clinical trial.

The short-term toxic effects of chemotherapy used in the adjuvant setting are generally well tolerated. Although a number of investigators have demonstrated a reduction in quality-of-life, most patients are able to maintain a reasonable level of function and emotional and social well-being during treatment.[107,108] Supportive therapy of the patient receiving systemic adjuvant chemotherapy has improved over the past decades. Increased attention to the impact of symptoms on quality-of-life may account for some of this improvement. In addition, more effective antiemetics have become available to assist in managing chemotherapy-induced nausea and vomiting, and colony-stimulating factors are often helpful in preventing febrile neutropenia, particularly in elderly patients or patients receiving dose-dense chemotherapy regimens. Despite the use of newer antiemetics for prevention of nausea and vomiting, many women still have difficulty with this side effect and delayed nausea and vomiting remains problematic in some patients. Aprepitant, a novel neurokinin-1 antagonist, may be considered in addition to serotonin receptor antagonists

and dexamethasone to improve outcomes for some patients receiving anthracycline-based chemotherapy, but clinicians should be aware of the potential for clinically significant drug–drug interactions between aprepitant and other drugs, including some chemotherapy. The use of growth factors to support some adjuvant chemotherapy regimens may be required (e.g., with dose-dense regimens), but should also be used with caution. Myeloid growth factors and erythropoietic stimulating agents (ESAs) have potential effects on cancer cells and the cellular environment that may negatively impact the antitumor effects of chemotherapy or enhance adverse effects related to the chemotherapy.[109] Although these effects are very controversial, the addition of growth factors to a regimen should be undertaken only after all risks and benefits are thoroughly considered.

Many other side effects are common with the chemotherapy regimens employed for treatment of early stage breast cancer and patients should be appropriately counseled regarding the likelihood of alopecia, weight gain, and fatigue. Patients who are menstruating will often experience a cessation of menses that may not return; cessation of menses may be accompanied by signs and symptoms of menopause. Deep vein thrombosis has been reported in women receiving combination chemotherapy regimens.[110] Leukemia and other hematologic disorders have long been associated with the alkylating agents (e.g., cyclophosphamide) and the topoisomerase II inhibitors (e.g., doxorubicin and epirubicin). Several studies have estimated a 0% to 1.5% cumulative incidence of leukemia and/or myelodysplasia after adjuvant chemotherapy with median follow-up of 3 to 11 years.[111] To date, the dose-dense regimens have not been associated with an excess rate of leukemias, but the follow-up on these trials is relatively short.

Cardiomyopathy induced by doxorubicin occurs in less than 1% of women whose total dose of doxorubicin is less than 320 mg/m^2.[112] This risk may be further decreased by use of continuous infusion doxorubicin. It should be noted that epirubicin in the adjuvant setting is usually given at a dose of 100 to 120 mg/m^2.[113] At this dose, epirubicin has an equal chance of causing cardiomyopathy as standard doxorubicin doses when both agents are given as bolus or short infusions. Taxanes are often associated with hypersensitivity reactions, peripheral neuropathy and/or myalgias and arthralgias for several days following the infusion.

It is important to note that the magnitude of survival benefit for adjuvant chemotherapy in stages I and II breast cancer is modest, with an absolute reduction in mortality of only 5% at 10 years for patients with negative axillary lymph nodes and 10% for patients with positive axillary lymph nodes. In addition, it is currently not possible to accurately predict who will attain this survival benefit. The advent of genetic prognostic tools, such as Oncotype DX, can help to identify patients who may derive little or no benefit from chemotherapy. However, these tests are only appropriate in specific subsets of patients. Studies have reported that most breast cancer patients would accept severe toxicity from treatment to achieve as little as a 1% to 5% improvement in survival.[89,90] Thus in the absence of the ability to predict who will benefit, it is likely that most patients with stage I and stage II breast cancer would choose adjuvant chemotherapy.

The optimal chemotherapy regimen for use in the adjuvant setting has yet to be identified and the choice of chemotherapy regimen for a specific patient is complex. Many adjuvant chemotherapy regimens are available, and the majority of these regimens have not been directly compared in randomized clinical trials. In some cases the choice of chemotherapy regimen may be geographic, particularly if a regimen has been developed and studied by a particular institution. Based on data from clinical trials and the previously mentioned pooled analysis, the concomitant or sequential addition of a taxane to an anthracycline-based chemotherapy regimen has become the standard of care for women with node-positive breast cancer. The use of taxanes in combination with anthracyclines is more controversial in patients with node-negative disease, and therefore taxanes may or may not be utilized in this patient population. Results from a single trial which evaluated a taxane-containing (non-anthracycline) regimen are available and this regimen may be an appropriate treatment in a subset of patients at low risk of disease recurrence. NCCN recommendations are purposefully vague, and they do not differentiate between patients with node positive or negative breast cancer. The NCCN has designated preferred chemotherapy regimens, as listed in Table 136–10, although detailed information is not provided regarding the rationale behind these designations.

Adjuvant Biologic Therapy As biologic agents continue to demonstrate significant activity against metastatic breast cancer, they are subsequently tested in the adjuvant setting. Trastuzumab is a monoclonal antibody targeted against the *HER2*-receptor protein. It has demonstrated significant survival benefits when administered with chemotherapy in women with metastatic, *HER2*-positive breast cancer. Several published or presented studies support the use of trastuzumab in combination with or sequentially following adjuvant chemotherapy for patients with early-stage, *HER2*-positive breast cancer (Table 136–11).[114–118] Results from these trials report up to a 50% reduction in the risk of recurrence with the addition of trastuzumab to an adjuvant chemotherapy regimen. While similar benefits are seen in the published trials to date, the chemotherapy regimens, sequence of administration and duration of trastuzumab differ (Table 136–11).

A meta-analysis of five clinical trials involving 9,739 women revealed superior DFS (RR, 0.62; 95% CI, 0.56-0.68; P <0.0001) and OS (RR, 0.66; 95% CI, 0.57-0.77; P <0.0001) in patients with *HER2*-positive breast cancer who received trastuzumab with chemotherapy compared to those that received chemotherapy alone.[119] This difference in DFS translated into a 38% overall lower relative risk for disease progression or death from any cause for patients who received trastuzumab.

Most of the regimens investigated in these adjuvant trials included an anthracycline and a taxane given concurrently with trastuzumab or sequentially prior to trastuzumab. From the available evidence, it appears that administration of a taxane with trastuzumab may be more effective than trastuzumab administered after chemotherapy. The benefit of sequential administration of trastuzumab has come into question since only one study (Herceptin Adjuvant Trial, HERA) has demonstrated a significant benefit with trastuzumab administered in this manner. The adjuvant use of trastuzumab without an anthracycline has been reported in one trial (Breast Cancer International Research Group 006) and from preliminary analyses appears to provide similar benefit with diminished adverse effects as compared with traditional anthracycline-containing adjuvant trastuzumab regimens. The duration of trastuzumab therapy in these adjuvant trials ranges from 9 to 52 weeks in the published studies. The optimal duration of trastuzumab therapy is unknown. In the United States, trastuzumab has been approved for adjuvant therapy of early-stage, *HER2*-positive breast cancer when given in combination with doxorubicin and cyclophosphamide followed by paclitaxel or docetaxel and the trastuzumab is initiated with the taxane and continued for 1 year (total duration of trastuzumab is 52 weeks). Trastuzumab has also been approved by the U.S. Food and Drug Administration (FDA) in combination with docetaxel and carboplatin followed by trastuzumab (for a total of 1 year), as well as administered alone for 1 year following anthracycline-based chemotherapy. These approvals are based on results from the NSABP/NCCTG (North Central Cancer Treatment Group) combined analysis, the HERA (Herceptin Adjuvant) trial, and the BCIRG 006 trial.[120] One year of trastuzumab, either concomitantly

with chemotherapy or sequentially after chemotherapy has become the standard duration of therapy in the United States and many other countries.

The incidence of adverse cardiac effects associated with the addition of trastuzumab appears to increase when an anthracycline is included in the regimen prior to administration of trastuzumab. In the previously mentioned meta-analysis, trastuzumab use resulted in an increased risk of class III/IV heart failure (RR, 7.60; 95% CI, 4.07-14.18; P <0.0001) compared with chemotherapy alone.[119] However, the higher risk of cardiac complications may be acceptable given the significant reductions in breast cancer recurrence and death rates. Sequential administration of trastuzumab after chemotherapy (as in the HERA trial) appears to produce a lower incidence of cardiac toxicity (severe congestive heart failure = 2% with trastuzumab). However, the definition of cardiac events in each trial was different. Concurrent administration of trastuzumab with an anthracycline is very controversial, potentially associated with higher rates of cardiac dysfunction (although not yet proven in this clinical setting), and should not be done outside the context of a clinical trial or an institution with extensive experience with this approach to trastuzumab dosing. Rare cases of interstitial pneumonitis were reported in the trastuzumab arm (nine patients) in the combined NSABP/NCCTG trial only. The causality of these events is unclear, but may be related to trastuzumab. Chemotherapy-related adverse effects are slightly more frequent with the addition of concurrent trastuzumab therapy, including neutropenia, infection and diarrhea, but these toxicities are easily managed and do not preclude the use of trastuzumab in patients with early stage breast cancer.

All of these adjuvant trials continued trastuzumab administration during adjuvant radiation therapy and hormonal therapy. The administration of trastuzumab during radiation therapy was evaluated in patients that participated in the N9831 clinical trial. Patients that received concurrent radiation therapy with adjuvant trastuzumab did not experience a significant increase in cardiac events or acute radiation-related adverse events with the exception of transient leukopenia.[121] Therefore, if radiation therapy is clinically indicated, trastuzumab is typically administered concomitantly with radiation.

CLINICAL CONTROVERSY

Trastuzumab clearly has improved the outcome for women with early-stage, *HER2*-positive breast cancer. However, the optimal trastuzumab-containing regimen remains unknown. Questions remain regarding optimal concurrent chemotherapy; optimal dose, schedule, and duration of trastuzumab therapy; and use of other concurrent therapeutic modalities. Many ongoing clinical trials hope to answer these questions. Also, while the addition of trastuzumab has improved DFS and OS, it is not effective for all women and issues regarding trastuzumab resistance are becoming more complex.

Many questions remain regarding the optimal use of trastuzumab in the adjuvant therapy of early stage breast cancer. The use of trastuzumab with chemotherapy in the adjuvant setting is now considered to be the standard of care for patients with node-positive and high-risk node negative *HER2*-positive breast cancer. A retrospective analysis of patients with tumors smaller than 1 cm demonstrated that patients with *HER2*-positive tumors have a lower recurrence free survival at 5 years as compared to patients with *HER2*-negative tumors (HR, 2.68; 95% CI, 1.44-5; $P = 0.002$).[122] Therefore, treatment with trastuzumab in patients with small, *HER2*-positive, node negative tumors may be considered. In the United States, only one study has analyzed the cost-effectiveness of adjuvant trastuzumab administration. Hillner estimated an incremental cost of about $50,000 per life-year gained based on data from the NCCTG/NSABP and HERA trials combined.[123] This figure is well below what has typically been considered acceptable for other therapeutic advances in the United States (e.g., dialysis, adjuvant chemotherapy for early-stage breast cancer), but borders on unacceptable for other countries with nationalized healthcare. While this type of discussion is far beyond the scope of this chapter, the reader is referred to the following reviews for further discussion regarding this topic.[124,125] Nonetheless, trastuzumab is a very effective, but costly, addition to adjuvant therapy, with apparent risks that should be discussed in detail with all patients with *HER2*-positive breast cancer prior to undergoing therapy. A similar approach has been used in the neoadjuvant treatment of *HER2*-positive breast cancer as well (see section on Locally Advanced Breast Cancer). Clinical trials involving other novel *HER2*-directed therapies, such as lapatinib, in the adjuvant and neoadjuvant settings are ongoing.

Adjuvant Endocrine Therapy 4 Hormonal therapies that have been studied in the treatment of primary or early stage breast cancer include tamoxifen, toremifene, oophorectomy, ovarian irradiation, luteinizing hormone-releasing hormone (LHRH) agonists and aromatase inhibitors. Choice of agent(s) depends on menopausal status and is based on a multitude of clinical trials completed in this setting that establish different roles for different therapies.

Tamoxifen was traditionally the gold standard adjuvant hormonal therapy and has been used in the adjuvant setting for more than three decades. Tamoxifen is antiestrogenic in breast cancer cells, but it appears to have estrogenic properties in other tissues and organs.[126,127] More recent studies show that tamoxifen and other similar drugs have many estrogenic and antiestrogenic effects that depend on the tissue and the gene in question, and they are more appropriately called selective estrogen receptor modulators (SERMs). Women receiving adjuvant tamoxifen therapy have reduced risk of recurrence and mortality as compared with women not receiving adjuvant tamoxifen therapy.[5] This observation, coupled with evidence of tolerability for tamoxifen, including beneficial estrogenic effects on the lipid profile and bone density, led to tamoxifen being the hormonal agent of choice for both pre- and postmenopausal women when compared with older, more toxic therapies (e.g., megestrol acetate). Premenopausal patients may derive equivalent benefit from ovarian ablation via surgery or administration of LHRH agonists when compared with tamoxifen.[5] In the United States, tamoxifen is generally considered the adjuvant hormonal therapy of choice for premenopausal women. However, many ongoing clinical trials are investigating the use of the LHRH agonists or oophorectomy instead of tamoxifen or in addition to tamoxifen or aromatase inhibitors in this group of women.

The optimal dose of tamoxifen is unclear. The EBCTCG overview showed that more (up to 40 mg/day) is not necessarily better for response rates.[5] Lower doses of tamoxifen (less than 20 mg/day) may be effective, but no clinical trials have addressed this question. Therefore the current recommended dose for tamoxifen in the adjuvant, metastatic, and preventive settings is 20 mg/day. Because tamoxifen has a long biologic half-life, it can be administered as a single daily dose. Adjuvant tamoxifen therapy is generally initiated shortly after surgery or as soon as pathology results are known and the decision to administer tamoxifen as adjuvant therapy is made.

When adjuvant tamoxifen is given with chemotherapy, it should be given after chemotherapy is completed. This recommendation is based on laboratory and clinical evidence from a phase III trial suggesting tamoxifen administered concurrently with chemotherapy may antagonize the beneficial effect of chemotherapy.[128] In the phase III clinical trial, administration of sequential tamoxifen resulted in a marginally superior DFS as compared to concurrent use of tamoxifen with chemotherapy (HR, 0.84; 95% CI, 0.70-1.01; $P = 0.061$).[128] Some clinicians also advocate the initiation of tamoxifen following completion of radiation therapy, but this subject is very controversial and few trials have addressed the issue of concurrent versus sequential hormone therapy and radiation therapy.

The optimal duration of tamoxifen therapy in the adjuvant setting is currently 5 years. Studies of prolonged administration (e.g., 10 years) have failed to demonstrate any advantage and in fact may be associated with a slightly worse survival.[129] Other clinical trials investigating durations of tamoxifen use longer than 5 years are ongoing.

The pharmacologic disposition of tamoxifen in humans is very complex and has only recently been elucidated (Fig. 136–6). Tamoxifen is now considered to be a prodrug. Although the parent compound has significant clinical activity, tamoxifen is metabolized through multiple enzymes including CYP3A4, CYP2C19, CYP2D6, and others to metabolites which appear to be more active than the parent compound.[130] The active metabolites 4-hydroxytamoxifen (4OH-TAM) and 4-hydroxy-N-desmethyltamoxifen (endoxifen) have nearly a 100-fold higher affinity for the estrogen receptor compared to tamoxifen. Endoxifen is present in the serum at a 6- to 12-fold higher concentration compared to 4OH-TAM, hence endoxifen is thought to be the most important metabolite for the clinical activity of tamoxifen. The formation of endoxifen is highly dependent on the enzymatic activity of CYP2D6. However, multiple other pathways may also be important for determining activity, including deactivation pathways (e.g., SULT-1-A1, UGT). Polymorphisms in CYP2D6 can lead to increased or decreased formation of endoxifen and may be related to improved or diminished clinical outcomes, respectively. Although there are clinical data to suggest that certain polymorphisms in CYP2D6 may result in poorer disease-free or relapse-free survival in patients receiving tamoxifen, these analyses are based mostly on retrospective analyses and contradictory studies also exist to refute these claims. Multiple commercially available assays for CYP2D6 are available, but widespread testing for patients receiving tamoxifen is not currently recommended based on available evidence.[47,88] Excellent reviews

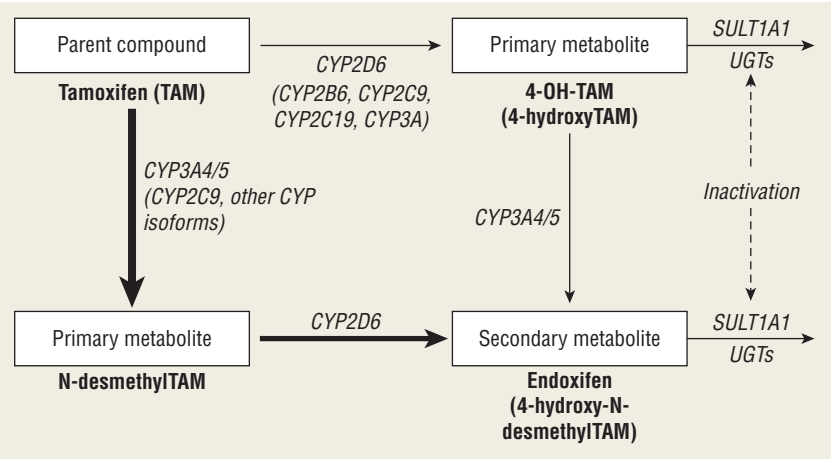

FIGURE 136-6. Tamoxifen metabolism.[131] Widths of the arrows approximate allocation of parent compound to various metabolites. See text for further explanation.

on this subject are available.[130] Potent inhibitors of CYP2D6, such as paroxetine and fluoxetine, may decrease levels of endoxifen in patients receiving tamoxifen.[131] The clinical outcomes related to such drug-drug interactions in an individual patient are largely unknown and depend on their underlying CYP2D6 genetic status (e.g., poor metabolizer, extensive metabolizer). However, common sense would dictate avoiding known strong inhibitors of CYP2D6, if possible, in patients receiving tamoxifen.

The most reliable information regarding the side effects of tamoxifen comes from the NSABP Breast Cancer Prevention Trial (P1).[55] This trial randomized 13,388 women 35 years of age or older who were at increased risk for breast cancer to placebo (n = 6,707) or to 20 mg/day of tamoxifen (n = 6,681) for 5 years. Although the primary finding of this study is that tamoxifen reduces the risk of invasive breast cancer by 49%, this study also provides an excellent opportunity to determine the risk of side effects associated with tamoxifen. Information was prospectively collected with regard to the occurrence of hot flashes, vaginal discharge, irregular menses, fluid retention, nausea, skin changes, diarrhea, and weight gain or loss. The self-administered depression scale and a global quality-of-life and a sexual function scale were administered at each follow-up visit. The only symptomatic differences noted between the placebo and tamoxifen group were related to hot flashes and vaginal discharge, both of which occurred more often in the tamoxifen group. No important differences between the two groups were observed in the various self-reporting instruments. Tamoxifen did not increase the risk of ischemic heart disease, but reduced the risk of hip radius and spine fractures. Of note, the rates of stroke, pulmonary embolism, and deep vein thrombosis were elevated in the tamoxifen group (stroke: RR, 1.59; pulmonary embolism: RR, 3.01; and deep vein thrombosis: RR, 1.60), particularly in women age 50 years or older. The rate of endometrial cancer was increased in the tamoxifen group (RR, 2.53), and this increased risk occurred predominantly in women age 50 years or older. The increased risk of endometrial carcinoma is similar in magnitude to that associated with postmenopausal estrogen replacement therapy and is likely a consequence of an estrogenic effect of tamoxifen on the endometrium. Some experts argue that this risk is acceptable because the endometrial cancer induced by tamoxifen is low stage, low grade, and easily treated with surgery or other means and does not pose a life-threatening risk to women. Tamoxifen was also associated with an increased risk of uterine sarcomas (a more aggressive form of endometrial cancer), but this risk appears to be lower than the more common endometrial cancers identified in the NSABP P-1 study.[132] Routine endometrial biopsy is not currently recommended for women receiving tamoxifen therapy. However, women receiving tamoxifen therapy should be counseled to have regular gynecologic examinations and immediately report unusual vaginal bleeding to their primary clinicians for further evaluation.

Toremifene is another marketed antiestrogen whose primary advantage is a lower estrogenic-to-antiestrogenic ratio as compared to tamoxifen (based on laboratory data).[133] Toremifene (60 mg orally daily) has been found to have efficacy similar to that of tamoxifen in metastatic disease and a generally similar side-effect profile.[134] Toremifene is currently indicated as an alternative to tamoxifen in patients with metastatic breast cancer, but studies are ongoing to evaluate its safety and efficacy in the adjuvant setting. Preliminary results from these trials indicate similar efficacy and safety, with possibly inferior bone protection with toremifene.[135,136] However, further follow-up is required to determine the long-term effects of toremifene in the adjuvant setting.

In premenopausal women, the use of LHRH-agonists or other means of ovarian ablation provides benefit in the adjuvant setting. In the EBCTCG overview analysis published in 2005, the overall benefit of ovarian ablation or suppression was significant compared with no treatment, but smaller than previously reported in 1996 (reduction in annual odds of recurrence = 25% ± 12% in women <40 years old and 29% ± 6% in women 40–49 years old).[5] Many of the ongoing trials with the LHRH agonists were not yet included in this analysis and most of the clinical trials analyzed included patients with hormone receptor-positive, -negative, and unknown status. In an update of this analysis, study inclusion was restricted to patients treated with ovarian suppression with LHRH agonists (not ovarian oblation or oophorectomy) and those patients with tumors known to be hormone receptor-positive.[137] The addition of a LHRH agonist reduced the rates of recurrence by 25%, deaths after recurrence by 28%, and all deaths by 27% in women younger than 40 years; no significant reductions in recurrence or death were noted in patient older than 40 years. Also, a similar benefit was observed with goserelin as compared with CMF chemotherapy in hormone-sensitive premenopausal breast cancer patients, but not in patients with hormone receptor-negative tumors.[137] It is not clear whether the benefit of chemotherapy in this population is a result of the actual effects of chemotherapy or a result of the endocrine effects of chemotherapy-induced menopause. Consequently, some studies have investigated the benefits of adding ovarian ablation or suppression to chemotherapy, either with or without tamoxifen. Results from these studies clearly indicate a benefit from ceasing menses, regardless of whether this is caused by chemotherapy or ovarian ablation or suppression.[137] It is not clear whether the addition of an LHRH agonist to tamoxifen is advantageous in women with hormone receptor-positive tumors who continue to menstruate after chemotherapy. The optimal duration of adjuvant

LHRH agonist use is unknown, with trials ranging from 18 months to 5 years of treatment. Multiple ongoing trials are attempting to answer this question; these trials include an LHRH agonist alone, with tamoxifen or with an aromatase inhibitor. Currently, the only trial with available results is a study by the Austrian Breast and Colorectal Cancer Study Group (ABCSG-12) which randomized premenopausal patients with hormone receptor-positive early stage breast cancer to 3 years of tamoxifen or anastrozole, both concomitantly with goserelin for ovarian suppression.[138] After a median follow-up of 48 months, there was no significant difference in DFS between the two groups. However, a tamoxifen-only arm was not included in this trial.

In postmenopausal women, aromatase inhibitors (AI) are gradually replacing tamoxifen in the adjuvant setting. Four different approaches to therapy have been undertaken with these new agents: (a) direct comparison with tamoxifen for adjuvant hormonal therapy, (b) sequential use after 5 years of adjuvant tamoxifen therapy, (c) sequential use after 2 to 3 years of adjuvant tamoxifen, and (d) 2 years of treatment with an AI followed by 3 years of adjuvant tamoxifen. Anastrozole and letrozole have been directly compared with tamoxifen as initial therapy in postmenopausal women with hormone receptor-positive, early stage breast cancer (ATAC [Arimidex, Tamoxifen, Alone or in Combination] Trial and BIG [Breast International Group] 1–98 Trial).[139,140] These comparisons show an advantage with the aromatase inhibitors over tamoxifen in terms of DFS. Other approaches to adjuvant hormonal therapy with AIs include sequential use of newer agents after either 5 years or 2 to 3 years of tamoxifen. In the MA-17 study, 5 additional years of letrozole was compared with placebo in postmenopausal breast cancer patients who had completed 5 years of tamoxifen therapy.[141] After a median follow-up of 2.4 years, letrozole was associated with superior estimated 4-year DFS as compared with placebo (93% vs 87%; P <0.001). Because of this difference, patients were unblinded and allowed to crossover to the active arm of therapy. In a pooled analysis of trials investigating a switch to an AI, 9,015 patients who had completed 2 to 3 years of adjuvant tamoxifen therapy were randomized to continue tamoxifen or crossover to anastrozole or exemestane for the remainder of 5 years.[142] The results of this analysis show a decreased risk of recurrence at 6 years following randomization in patients who switched to an AI as compared to those who continued with tamoxifen alone (12.6% vs 16.0%; P <0.00001). The BIG 1–98 trial which compared letrozole with tamoxifen also included two separate arms which investigated the value of switching from tamoxifen to an AI or vice versa. With 71 months of follow-up, the sequential arms did not improve estimated 5-year DFS compared to letrozole alone in either comparison.[143] Clinical trials are also investigating longer durations of AI use to assess the benefits and harms of continued estrogen deprivation, the results of which are greatly anticipated.

Most national and international guidelines currently recommend incorporation of an AI into the adjuvant hormonal therapy regimen for all postmenopausal, hormone-sensitive breast cancers.[47] The current NCCN guidelines for breast cancer management state that any of the following are acceptable endocrine therapy regimens for these women: (a) an AI for 5 years (or longer, based on expert opinion); (b) tamoxifen for 2 to 3 years followed by an AI for a total of 5 years of endocrine therapy; or (c) tamoxifen for 5 years followed by an AI for another 5 years (total of 10 years of endocrine therapy).[47] The NCCN panel believes that the three available AIs (anastrozole, letrozole, and exemestane) have similar antitumor efficacy and toxicity profiles and many other clinicians agree. Therefore, the optimal hormonal therapy regimen in the adjuvant setting has yet to be determined, and results from ongoing trials are eagerly awaited to more clearly define a treatment strategy for women facing this clinical dilemma.

AIs are generally well tolerated. Adverse effects include bone loss/osteoporosis, hot flashes, myalgia/arthralgia, vaginal dryness/atrophy, mild headaches, and diarrhea. Although concerns surrounding loss of bone density and an increased risk of osteoporosis are evident in these adjuvant trials, the overall impact on quality-of-life and long-term survival are still being evaluated. Bisphosphonates are coadministered with the AI in many patients in the metastatic setting and may also be beneficial in the adjuvant setting. Other adverse events that are worrisome include questionable effects on the cardiovascular system (e.g., hypercholesterolemia), cognitive functioning and joint health. Longer follow-up from these trials will continue to provide valuable information to guide treatment decisions and side-effect management.

CLINICAL CONTROVERSY

The optimal use of antiaromatase agents in the adjuvant setting for postmenopausal women with hormone receptor-positive tumors is controversial. Multiple studies have been published with results indicating a benefit to regimens that include an aromatase inhibitor as initial therapy or after tamoxifen. However, many questions remain as to the optimal drug, dose, sequence, and duration of therapy for these agents.

In summary, tamoxifen has been used in the adjuvant setting for nearly 30 years and has a very well-defined safety and efficacy profile in this setting. Although it is difficult to define the role of new therapies given the lengthy history of tamoxifen, the role of tamoxifen in the adjuvant setting is changing with the incorporation of newer agents either concurrently (e.g., LHRH agonists) or sequentially (e.g., AIs).

LOCALLY ADVANCED BREAST CANCER (STAGE III)

5 *Locally advanced breast cancer* generally refers to breast carcinomas with significant primary tumor and nodal disease, but in which distant metastases cannot be documented. A wide variety of clinical scenarios can be seen within this group of patients, including neglected tumors that have spread locally, to inflammatory breast cancers that are a unique clinical entity. Inflammatory breast cancer is associated with similar clinical findings as compared to other neglected, locally advanced breast tumors (e.g., erythema representing skin involvement). The distinction between the two diagnoses lies in the rapidity of onset of symptoms. Many locally advanced breast cancers are diagnosed in patients who have had symptoms for months to years and have neglected to seek medical attention. Although these women have a poor prognosis because of the delay in diagnosis, they are not classified as inflammatory breast cancer. The hallmark of inflammatory breast cancers is the rapid onset of symptoms within weeks to months, including erythema of the skin with or without a detectable underlying breast mass. These patients are often inappropriately treated for cellulitis with antibiotics for several weeks to months. Because of the aggressive nature of this disease, a delay in diagnosis can be fatal for some of these women.

The natural history of locally advanced breast cancer shows that even when local-regional control is accomplished, systemic relapse and death from breast cancer eventually occur in most patients if systemic therapy is not utilized.[144] That observation led to interest in the use of neoadjuvant or primary chemotherapy in locally advanced breast cancer, which renders inoperable tumors resectable, and can increase rates of BCT. Other potential benefits related

to early initiation of systemic therapy include delivery of drugs through an intact vasculature, in vivo assessment of response to therapy, and the opportunity to study the biologic effects of the systemic treatment. However, this approach to therapy also results in a loss of standard, well-validated pathologic prognostic markers, such as initial tumor size (measured by pathologic examination) and the number of axillary lymph nodes involved. Also, as discussed earlier, OS with adjuvant as compared with neoadjuvant chemotherapy is similar. However, in light of other benefits gained with neoadjuvant therapy, these two factors may not be enough to continue to drive the practice of primary surgery. The topic of adjuvant versus neoadjuvant systemic therapy is fraught with controversy, but the many advantages of neoadjuvant, primary systemic therapy are continuing to drive an increase in the number of operable patients offered this treatment modality.[145] For patients with inoperable breast cancer, including inflammatory breast cancer, the initial approach to therapy should be chemotherapy with the goal of achieving resectability. The NCCN guidelines addressing the management of locally advanced disease recommend primary chemotherapy with an anthracycline-containing regimen with or without a taxane.[47]

After neoadjuvant chemotherapy, most tumors respond with more than a 50% decrease in tumor size; approximately 70% of patients experience a reduction in their stage of disease. The chemotherapy regimens used in this setting are similar to those used in the adjuvant setting, but the regimens usually include an anthracycline, incorporate a taxane in some manner, and may have higher dose density or dose intensity. For patients with *HER2*-positive tumors, the incorporation of trastuzumab with chemotherapy is appropriate.[146] For more detailed information regarding the specific regimen-related information, the reader is referred to the referenced review.[147] Neoadjuvant endocrine therapy may be an option for patients who have unresectable hormone receptor-positive tumors who are unable to receive chemotherapy (e.g., multiple comorbid conditions).[148]

Local therapy usually follows chemotherapy, and the extent of surgery is determined by response to chemotherapy, the wishes of the patient, and the cosmetic results likely to be achieved. However, many patients may be able to have BCT if an acceptable response to chemotherapy is achieved. Adjuvant radiation therapy should be administered to all locally advanced breast cancer patients to minimize local recurrences, regardless of the type of surgery used for that individual patient (e.g., mastectomy or segmental mastectomy). Inoperable tumors that are unresponsive to systemic chemotherapy may require radiation therapy for local management and may not be eligible for surgical resection after radiation. These patients are not commonly seen, but have a very poor prognosis. For most patients in this category, cure is still the primary goal of therapy and can be achieved in a large number of patients when all treatment modalities are employed.

METASTATIC BREAST CANCER (STAGE IV)

6 The goal of therapy with early and locally advanced breast cancer is to cure the disease. After it has advanced beyond local–regional disease, breast cancer is currently incurable. However, some patients live for many years with metastatic disease, making this a chronic disease requiring long-term management strategies that incorporate improvements and/or maintenance of quality of life. The goals of treatment of metastatic breast cancer are to improve symptoms and quality-of-life and extend survival. Thus it is important to choose therapy with optimal activity while minimizing toxicities. Treatment of metastatic breast cancer with cytotoxic, biologic, or endocrine therapy often results in regression of disease and improvements in quality-of-life. In patients who respond to therapy, duration of survival is also increased. The choice of therapy for metastatic disease is based on the site of disease involvement and presence or absence of certain characteristics. The most important factor predicting response to endocrine therapy is the presence of estrogen and progesterone receptors in the primary tumor tissue. Fifty percent to 60% of patients with ER-positive tumors and 75% to 80% of patients with ER- and PR-positive tumors will respond to hormonal therapy, whereas those with ER- and PR-negative tumors have a less than 10% response rate. Thus the most important factor determining choice of endocrine versus cytotoxic chemotherapy is the presence of hormone receptors in the primary breast tumor. Site of disease is also important because endocrine therapy is more likely to be effective in patients with bone and soft-tissue metastases. Patients with asymptomatic visceral involvement (e.g., liver or lung) may be candidates for hormonal therapy, depending on the clinical circumstance (hormones usually work more slowly than chemotherapy). Patients with symptomatic visceral and/or central nervous system involvement generally have more rapidly growing cancers that require chemotherapy. Endocrine therapy is the treatment of choice for patients with hormone receptor-positive tumors who exhibit the first sign of metastatic disease in soft tissue, bone, or pleura, because of the equal probability of response to hormonal therapy as compared to chemotherapy, and a preferable toxicity profile with endocrine therapy.

7 Patients who respond to initial endocrine therapy often respond to a second (or even third) hormonal manipulation. But the response rate is lower and duration of response is shorter with second (and third) hormonal manipulations. Patients are sequentially treated with endocrine therapy until their tumors cease to respond or the patient ceases to benefit from endocrine therapy, at which time cytotoxic chemotherapy can be administered. Concurrent administration of different hormonal therapies or chemotherapy plus hormones is generally not used in the setting of metastatic breast cancer because of lack of increased efficacy and evidence of increased toxicity. Women with hormone receptor-negative tumors, with rapidly progressive or symptomatic lung, liver, or bone marrow involvement, and those with progressive disease while on initial endocrine therapy are usually treated initially with cytotoxic chemotherapy. Patients with tumors that have *HER2* protein overexpression or gene amplification should be considered for treatment with *HER2*-targeted therapy alone or with chemotherapy or endocrine therapy. All breast cancer patients with metastases to the bone should be considered for treatment with an intravenous bisphosphonate (e.g., pamidronate or zoledronic acid) as these agents have been shown to decrease the rates of skeletal-related events (SREs) such as fractures, spinal cord compression, pain, and/or the need for radiation to the bones or surgery.[149] These agents do not act as anticancer agents and should be coadministered with chemotherapy, endocrine therapy and/or *HER2*-targeted therapy.

Endocrine Therapy

6 The pharmacologic goal of endocrine therapy for breast cancer is to either (a) decrease circulating levels of estrogen or (b) prevent the effects of estrogen at the breast cancer cell (targeted therapy) by blocking the hormone receptors or downregulating the presence of those receptors. Achievement of the first goal depends on the menopausal status of the patient, but achievement of the second goal is independent of menopausal status. Many endocrine therapies are available to target either goal of therapy, and combinations of drugs with different mechanisms of action have also been investigated. Unfortunately, most combinations have not demonstrated any efficacy benefits over single-agent hormone therapy, but have increased toxicity. Therefore, combinations of endocrine agents for breast cancer are generally not recommended outside the context of a clinical trial. One exception to this statement is the combination of LHRH agonist with an AI or SERM (as discussed below). Sequential

TABLE 136-12 Endocrine Therapies Used for Metastatic Breast Cancer

Class	Drug	Dose	Side Effects
Aromatase inhibitors			
Nonsteroidal	Anastrozole	1 mg orally daily	Hot flashes, bone loss/osteoporosis, arthralgias, myalgias, headaches, diarrhea, mild nausea
	Letrozole	2.5 mg orally daily	
Steroidal	Exemestane	25 mg orally daily	
Antiestrogens			
SERMs	Tamoxifen	20 mg orally daily	Hot flashes, vaginal discharge, mild nausea, thromboembolism, endometrial hyperplasia/cancer
	Toremifene	60 mg orally daily	
SERDs	Fulvestrant	250 mg IM every 28 days	Hot flashes, injection site reactions, possibly thromboembolism
LHRH analogs	Goserelin	3.6 mg SC every 28 days	Hot flashes, amenorrhea, menopausal symptoms, injection site reactions (extended formulations of more than 28 days are not recommended for the treatment of breast cancer)
	Leuprolide	3.75 mg IM every 28 days	
	Triptorelin	3.75 mg IM every 28 days	
Progestins	Megestrol acetate	40 mg orally 4 times a day	Weight gain, hot flashes, vaginal bleeding, edema, thromboembolism
	Medroxyprogesterone	400–1,000 mg IM every week	
Androgens	Fluoxymesterone	10 mg orally twice a day	Deepening voice, alopecia, hirsutism, facial/truncal acne, fluid retention, menstrual irregularities, cholestatic jaundice
Estrogens	Diethylstilbestrol	5 mg orally 3 times a day	Nausea/vomiting, fluid retention, anorexia, thromboembolism, hepatic dysfunction, myocardial infarction
	Ethinyl estradiol	1 mg orally 3 times a day	
	Conjugated estrogens	2.5 mg orally 3 times a day	

LHRH, luteinizing hormone-releasing hormone; SC, subcutaneous; SERD, selective estrogen receptor downregulator SERM, selective estrogen receptor modulator.

use of endocrine agents is now becoming popular in the adjuvant setting and may play a role in the metastatic setting when a patient is progressing on one agent after an initial response. These patients are often treated with a series of endocrine agents, usually over several years, before chemotherapy is considered.

Until recently, there was little evidence that the response or survival benefit from one endocrine therapy was clearly superior to that achieved with other therapies. Randomized controlled trials showed that antiestrogens, progestins, aminoglutethimide, estrogens, and androgens; and surgical procedures including oophorectomy, adrenalectomy, and hypophysectomy were equivalent in patients with metastatic breast cancer. Consequently, the choice of a particular endocrine therapy was based primarily on toxicity and patient preference (Table 136–12). Based on these criteria, tamoxifen was the preferred initial agent when metastases were present, except when the patient received adjuvant tamoxifen at the same time or within 1 year of occurrence of metastatic disease. In these cases, other agents were generally employed.

Over the past decade, results of clinical trials of third-generation AIs have changed the treatment of metastatic breast cancer, as well as of early-stage breast cancer (as was noted previously). In postmenopausal and castrated women, the main source of estrogen is derived from the peripheral conversion of androstenedione, produced by the adrenal gland, into estrone and estradiol. This conversion requires the enzyme aromatase. Aromatase also catalyzes the conversion of androgens to estrogens in the ovary in premenopausal women and in extraglandular tissue, including the breast and breast cancer cells, in postmenopausal women. Therefore, AIs effectively reduce the levels of circulating estrogens and estrogens in the target organ. Aminoglutethimide was the prototype aromatase inhibitor, but was a nonspecific, weak enzyme inhibitor associated with many toxicities and is no longer available in the United States. Several analogs and derivatives of aminoglutethimide, as well as novel endocrine compounds, have been tested over the years to try and improve on the therapeutic ratio of this agent. Third-generation AIs now available include anastrozole, letrozole, and exemestane. These agents have far greater selectivity and higher potency for the aromatase enzyme than aminoglutethimide. A major advantage of these newer compounds is their preferable toxicity profile, which consists mainly of bone loss/osteoporosis, mild nausea, hot flashes, arthralgias/myalgias, and mild fatigue. Anastrozole and letrozole are nonsteroidal compounds that exhibit reversible, competitive inhibition of aromatase. These are triazole compounds and have no intrinsic hormonal activity. Exemestane is a steroidal compound which binds irreversibly to aromatase, forming a covalent bond. While this mechanism may have theoretical advantages to the reversible binding seen with the nonsteroidal agents, there is no clinical evidence that this drug is superior to other agents in this class. Exemestane does possess some androgenic properties at doses that are much higher than those used clinically and may have some unique toxicities in some patients.

These third-generation AIs have been compared with megestrol acetate (MA) as second-line therapy in postmenopausal women with positive or unknown hormone receptor status who have progressed while on tamoxifen therapy. Although response rates with these agents have not been significantly better time-to-progression, and OS are significantly better than MA with at least two of the three AIs (anastrozole and exemestane).[150] Rates of clinical benefit (objective response + stabilization of disease for 24 weeks) are also improved with the AIs. Clinical benefit, a category of response used in metastatic breast cancer clinical trials, is another clinically relevant endpoint because it is associated with similar OS compared with patients who have objective responses.[151] Tolerability is also improved with the AIs as compared with MA. Toxicity patterns showed more nausea, vomiting, and hot flashes with the AI and more weight gain, fluid retention, and thromboembolism with MA. All three agents are approved for second-line therapy of advanced breast cancer in postmenopausal women, and have largely replaced MA for second-line therapy.

Both anastrozole and letrozole are also approved for first-line therapy of advanced breast cancer in postmenopausal women. Large randomized trials have compared these agents to tamoxifen and found similar response rates and a longer median time to progression for patients receiving the selective AI.[150] A consistent finding in these trials was a lower incidence of thromboembolic events and vaginal bleeding in patients who received selective AIs. Based on these results, many experts have concluded that the new AIs are superior to tamoxifen as first-line therapy for advanced breast cancer in postmenopausal women. Although not FDA approved for this indication, exemestane has been compared with tamoxifen as front-line therapy for hormone-sensitive metastatic breast cancer. In one, large randomized phase III trial, exemestane demonstrated

a modest advantage over tamoxifen in terms of progression-free survival (PFS) (9.9 vs 5.8 months; $P = 0.121$).[152] While this difference failed to reach statistical significance, the numerical difference is quite large confirming the advantage of exemestane as first-line therapy for metastatic breast cancer. Use of a steroidal aromatase inhibitor (exemestane) after a patient progresses on a nonsteroidal inhibitor (anastrozole or letrozole) may provide some benefit and is a common practice based on limited data. The opposite sequence also has shown some benefit; thus patients may receive two AIs (first line and second line, sequentially), especially those patients who progress while on adjuvant tamoxifen therapy.

The AIs should only be used in postmenopausal women. Pre- or perimenopausal women, whose ovaries are functioning, are inappropriate candidates for these therapies, at least based on the available evidence. Use of the AIs in addition to ovarian ablation (e.g., oophorectomy or LHRH agonists) is under investigation. Interestingly, the use of AIs in men with advanced breast cancer is controversial due to concerns that the pituitary feedback loop may be activated, increasing the levels of FSH, LH, and possibly testosterone. Therefore, while objective responses are seen with single-agent AI therapy in men with breast cancer, consensus has yet to be reached regarding the clinical utility of these agents in men and some clinicians are investigating the combination of an LHRH agonist with an AI in this population.[153] Until further clinical trials are completed, the efficacy and safety of this treatment approach are unknown.

Antiestrogens bind to estrogen receptors, which inhibit receptor-mediated gene transcription and therefore block the effect of estrogen on the end target. This class of agents is now subdivided into two pharmacologic categories, SERMs and pure antiestrogens. SERMs include tamoxifen and toremifene (and raloxifene for breast cancer risk reduction in high-risk women) and demonstrate tissue-specific activity, both estrogenic and antiestrogenic, as described previously. The agonistic activity is thought to be responsible for many of the adverse reactions seen with these agents, including the increased risk of endometrial cancer, and has led to the development of pure estrogen receptor antagonists that lack estrogen agonist activity. Pure antiestrogens are a new class of agents and are also referred to as selective estrogen receptor downregulators (SERDs). These molecules bind to the ER, inhibit estrogen binding, and degrade the drug-ER complex, thus decreasing the amount of ER on the tumor cell surface. Fulvestrant is currently the only pure antiestrogen commercially available in the United States.

Tamoxifen is generally considered to be the antiestrogen of choice in premenopausal women with metastatic breast cancer who have hormone receptor-positive tumors. Tamoxifen is usually administered in 20 mg once-daily doses. A tamoxifen dose of 20 mg/day reaches a steady-state concentration after about 4 months of therapy. The half-life of tamoxifen during chronic dosing is 7 days. Serum tamoxifen concentrations can be detected 6 weeks after discontinuation of therapy. Thus the maximum beneficial effects of tamoxifen are not observed for at least 2 months following initiation of therapy, and it is unlikely that symptoms of metastatic disease will return, even if patients miss several doses. The toxicities of tamoxifen are described in the Adjuvant Endocrine Therapy section above. The only additional toxicity that may be observed in the setting of metastatic breast cancer (specifically bone metastases) is a tumor flare and/or hypercalcemia, which occurs in approximately 5% of patients following the initiation of any SERM therapy and is not an indication to discontinue SERM therapy. It is generally accepted that this reaction is associated with response to endocrine therapy, but patients who do not experience such a reaction may still respond. This reaction is seen less frequently with the concurrent use of bisphosphonates as a result of their inhibition of osteoclasts, subsequently preventing the release of calcium from the bone.

Toremifene is another commercially available SERM for the treatment of breast cancer. It exhibits similar efficacy and tolerability compared with tamoxifen in the metastatic setting and is given at a dose of 60 mg daily. The same issues apply to toremifene as were discussed with tamoxifen. Cross-resistance to toremifene has been demonstrated in patients with tamoxifen-refractory disease.[154] Thus at the current time, toremifene appears to be an alternative to tamoxifen in postmenopausal patients with positive or unknown hormone receptor status with metastatic breast cancer. Raloxifene, another SERM, received approval in December 1997 for prevention of osteoporosis in postmenopausal women. Available data with raloxifene as a treatment for breast cancer show very low response rates and no clinical benefit. Consequently, use of this agent for breast cancer treatment should be discouraged. Investigation into the use of raloxifene for breast cancer risk reduction in high-risk women has recently been reported (see Prevention and Early Detection).

Fulvestrant is approved for the second-line therapy of postmenopausal metastatic breast cancer patients with hormone receptor-positive tumors. It is given as an intramuscular injection every 28 days and is marketed as a single injection of 5 mL. Studies have compared this agent to anastrozole, exemestane and tamoxifen in the treatment of postmenopausal women with metastatic breast cancer. Biologically, fulvestrant should produce similar outcomes in premenopausal women, but no data exist to confirm the safety or efficacy in premenopausal women. In the comparative trials with fulvestrant and an AI (anastrozole or exemestane), similar efficacy and safety were demonstrated with both agents when given after patients progressed on tamoxifen therapy.[155] When compared directly with tamoxifen, time-to-progression was slightly shorter in the fulvestrant arm but the difference did not reach statistical significance.[155] That trial failed to confirm statistical noninferiority, which indicates that the trial could not show that fulvestrant was equivalent to tamoxifen. Adverse events related to fulvestrant include injection-site reactions, hot flashes, asthenia, and headaches. The FDA-approved dose of fulvestrant is 250 mg given intramuscularly every 28 days. This agent is covered by Medicare and is a good option for patients who are unable to take an oral medication. Other dosing strategies have been investigated and appear to be safe and effective. The optimal dose of fulvestrant is widely debated and many strategies exist. Often reimbursement or insurance coverage dictates which dose is used.

Another goal of hormonal therapy in premenopausal women is to reduce estrogen production with surgery, irradiation, or medication. No difference in the overall response rate has been found in two randomized trials of tamoxifen and oophorectomy in premenopausal women. However, the secondary response rate to oophorectomy after tamoxifen treatment was somewhat higher than the response to tamoxifen after primary oophorectomy (33% vs 11%).[156,157] Based on this finding, some experts suggest that tamoxifen does not completely antagonize available estrogen, particularly in premenopausal women. Ovarian ablation (surgically or chemically) is still commonly used in some parts of the United States and is considered by many specialists to be the endocrine therapy of choice in premenopausal women. The mortality rate with surgical oophorectomy is low, usually less than 3% in appropriately selected patients. Irradiation of the ovaries was a means of castration many years ago, but was associated with multiple complications and is no longer performed for these purposes. Chemical castration with LHRH analogs is increasingly used instead of oophorectomy in premenopausal women.

Medical castration with LHRH analogs induce remission in about one third of unselected premenopausal metastatic breast cancer cases. The mechanism of action of LHRH analogs in

breast cancer is downregulation of LHRH receptors in the pituitary. Decreased levels of luteinizing hormone subsequently lead to a decrease in estrogen to castrated levels. Thus the effect of LHRH analogs on circulating estrogen levels in premenopausal breast cancer simulates oophorectomy. The three agents available and utilized in the United States are leuprolide, goserelin, and triptorelin, but only goserelin is approved for the treatment of metastatic breast cancer. These agents are administered as an injection every 4 weeks (all products have extended formulations, lasting 3 months to 1 year, but they are not recommended for the treatment of breast cancer) and are associated with minimal side effects including amenorrhea, bone loss/osteoporosis, hot flashes, and occasional nausea (Table 136–12). LHRH agonists may also produce a flare response because of an initial surge in leuteinizing hormone and estrogen production for the first 2 to 4 weeks of LHRH agonist administration. This flare response is similar to that seen with tamoxifen and patients with high volume disease should be monitored for increasing pain and/or hypercalcemia during the initiation period. A meta-analysis was conducted of several trials that combined tamoxifen and LHRH agonists versus LHRH agonists alone in premenopausal patients with metastatic breast cancer.[158] With a median follow-up of 6.8 years, there was a significant survival benefit and PFS benefit in favor of the combined treatment. The overall response rate was significantly higher with combined endocrine treatment. However, this analysis did not compare tamoxifen alone to the combination of an LHRH agonist with tamoxifen. Therefore if an LHRH agonist is used as first-line therapy for metastatic breast cancer, it should be used in combination with tamoxifen. But if tamoxifen is used as first-line therapy for metastatic breast cancer, the addition of a LHRH agonist is controversial because of the lack of clinical data to support any additional benefit.

Progestins such as MA and medroxyprogesterone acetate have been compared with tamoxifen in randomized trials and have been found to yield equivalent response rates. Medroxyprogesterone acetate is more frequently used in Europe, while MA is more frequently used in the United States. Based on efficacy and tolerability, these agents are generally reserved as third-line therapy after patients have failed an AI and an antiestrogen (tamoxifen, toremifene, or fulvestrant). The most common dose used for megestrol acetate is 160 mg/day. The most common side effect is weight gain, occurring in 20% to 50% of patients. Patients experiencing weight gain may also have fluid retention, but fluid retention is not totally responsible for the weight gain. In cachectic cancer patients, the weight gain may be desirable, but this is not uniformly true of all patients with metastatic breast cancer. Other side effects associated with progestins include vaginal bleeding in 5% to 10% of patients either while taking the progestational agent or when it is discontinued, and less than a 10% incidence of hot flashes. Thromboembolic complications are also associated with these agents.

High-dose estrogens and androgens are rarely used today because of their side effect profile and the availability of better tolerated alternatives (e.g., AIs). About one third of patients placed on high-dose estrogens will discontinue them because of side effects, the most important of which are thromboembolic events, vomiting, and fluid retention. Less common side effects include areolar hyperpigmentation, breast tenderness and engorgement, vaginal discharge, incontinence, hot flashes, and phlebitis. All the effective androgens cause masculinizing effects, including hirsutism and acne, in more than 50% of patients. The mechanism by which these agents exert a therapeutic effect in breast cancer is unknown. However, these agents may inhibit aromatase among other pharmacologic effects that antagonize estrogen. Approximately 20% response rates were reported in clinical trials conducted in the 1960s and 1970s in unselected groups of breast cancer patients treated with androgens.

Cytotoxic Therapy

8 Cytotoxic chemotherapy is eventually required in most patients with metastatic breast cancer. Patients with hormone receptor-negative tumors require chemotherapy as initial therapy of metastases. Patients with hormone-sensitive tumors who initially respond to hormonal manipulations eventually cease to respond and go on to require chemotherapy. Combination chemotherapy results in an objective response in approximately 60% of patients previously unexposed to chemotherapy. Most patients have partial responses, and complete disappearance of disease occurs in fewer than 10% of patients treated. The median duration of response is 5 to 12 months, but some patients will have an excellent response to an initial course of chemotherapy and may live 5 to 10 years or longer without evidence of disease. Median survival of patients after treatment with commonly used drug combinations for metastatic breast cancer ranges between 14 and 33 months. The median time to response ranges from 2 to 3 months in most studies, but this period depends on the site of measurable disease and can range from 3 weeks (skin and lymph node metastases) to 18 weeks (bone metastases). Once a chemotherapy regimen has been initiated, it is usually continued until there is unequivocal evidence of progressive disease or intolerable side effects. Table 136–13 lists some selected chemotherapy agents employed in the metastatic setting.

Factors associated with an increased likelihood of response include a good performance status, a limited number (one to two) of disease sites (or involved organ systems), and a prolonged previous response to chemotherapy or hormonal therapy (i.e., long disease-free interval). Patients who have progressive disease during chemotherapy have a lower likelihood of response to a different type of chemotherapy. However, this is not necessarily true for patients who are given chemotherapy after some interval during which they have received no chemotherapy. Patients may actually be retreated with a regimen they received earlier if some time has passed since receiving the similar drugs (e.g., several years), but this is rarely done because of the large number of agents now available to treat breast cancer. Patients who do not respond to endocrine therapy are as likely to respond to chemotherapy as patients who are treated with chemotherapy as their initial treatment modality. Age, menopausal status, and receptor status do not appear to be directly associated with response to chemotherapy. There continues to be much debate surrounding the potential association between hormone receptor status and response to chemotherapy (e.g., ER status and anthracyclines).

A number of chemotherapeutic agents have demonstrated activity in the treatment of breast cancer, including doxorubicin, epirubicin, paclitaxel (conventional and protein bound), docetaxel, capecitabine, fluorouracil, cyclophosphamide, methotrexate, vinblastine, vinorelbine, gemcitabine, mitoxantrone, mitomycin-C, thiotepa, and melphalan. The most active classes of chemotherapy in metastatic breast cancer are the anthracyclines and the taxanes, producing response rates as high as 50% to 60% in patients who have not received prior chemotherapy for metastatic disease.[159] Paclitaxel was FDA approved in 1994 for single-agent treatment of metastatic breast cancer for patients who had relapsed following therapy with a doxorubicin-containing regimen. Weekly administration of paclitaxel results in higher response rates, time-to-progression, and survival in addition to a more favorable side-effect profile as compared with every 3-week administration.[160] The most useful weekly dose in the metastatic setting appears to be 80 mg/m^2/week with no breaks in therapy. With this approach, the toxicity profile of paclitaxel changes with less myelosuppression and delayed onset of peripheral

TABLE 136-13 Selected Chemotherapy Regimens for Metastatic Breast Cancer

Single-Agent Chemotherapy	
Paclitaxel[a,b]	**Vinorelbine**[c]
Paclitaxel 175 mg/m² IV over 3 hours Repeat cycles every 21 days ***or*** Paclitaxel 80 mg/m²/week IV over 1 hour Repeat dose every 7 days	Vinorelbine 30 mg/m² IV, days 1 and 8 Repeat cycles every 21 days ***or*** Vinorelbine 25–30 mg/m²/week IV Repeat cycles every 7 days (adjust dose based on absolute neutrophil count; see product information)
Docetaxel[d,e]	**Gemcitabine**[f]
Docetaxel 60–100 mg/m² IV over 1 hour Repeat cycles every 21 days ***or*** Docetaxel 30–35 mg/m²/week IV over 30 minutes Repeat dose every 7 days	Gemcitabine 600–1,000 mg/m²/week IV, days 1, 8, and 15 Repeat cycles every 28 days (may need to hold day 15 dose based on blood counts)[g]
Protein-bound Paclitaxel[g,h]	**Ixabepilone**[i]
Protein-bound Paclitaxel 260 mg/m² IV over 30 minutes Repeat cycles every 21 days ***or*** Protein-bound Paclitaxel 100–150 mg/m² IV over 30 minutes on days 1, 8, and 15 Repeat cycle every 28 days	Ixabepilone 40 mg/m² IV over 3 hours Repeat cycles every 21 days
Capecitabine[j]	**Liposomal doxorubicin**[k]
Capecitabine 2,000–2,500 mg/m² per day orally, divided twice daily for 14 days Repeat cycles every 21 days	Liposomal doxorubicin 30–50 mg/m² IV over variable duration Repeat cycles every 28 days
Combination Chemotherapy Regimens	
Docetaxel + capecitabine[l]	**Paclitaxel + Gemcitabine**[m]
Docetaxel 75 mg/m² IV over 1 hour, day 1 Capecitabine 2,000–2,500 mg/m² per day orally divided twice daily for 14 days Repeat cycles every 21 days	Paclitaxel 175 mg/m² IV over 3 hours, day 1 Gemcitabine 1250 mg/m² IV days 1 and 8 Repeat cycles every 21 days
Ixabepilone + capecitabine[i]	**Paclitaxel + bevacizumab**[n]
Ixabepilone 40 mg/m² IV over 3 hours, day 1 Capecitabine 1,750–2,000 mg/m²/day orally divided twice daily for 14 days Repeat cycles every 21 days	Paclitaxel 90 mg/m² IV over 1 hour, days 1, 8, and 15 Bevacizumab 10 mg/kg IV over 30–90 minutes, days 1 and 15 Repeat cycles every 28 days

neuropathy, but slightly more fluid retention and skin and nail changes. Although the incidence of hypersensitivity reactions is also slightly less at these lower doses (requiring fewer premedications) it remains at approximately 3%, despite incorporation of all available preventive measures.

Docetaxel has also demonstrated high single-agent activity against metastatic breast cancer. It received FDA approval in 1995 for treatment of metastatic breast cancer for patients with relapse following therapy with doxorubicin-containing regimens. Impressive overall response rates of 54% to 68% were reported in four studies of docetaxel 100 mg/m² as first-line chemotherapy. As compared with paclitaxel (175 mg/m² over 3 hours every 3 weeks), docetaxel (100 mg/m² every 3 weeks) was associated with longer time-to-progression (HR, 1.64; $P < 0.0001$) and OS (HR, 1.41; $P = 0.03$).[161] As noted above, this is not the most effective dose or schedule of paclitaxel. Nonetheless, this difference appears to be real, although clinically irrelevant at this time. Myelosuppression is the major dose-limiting toxicity of docetaxel. Nonhematologic toxicities include fatigue, mucosal toxicity, mild-to-moderate nausea and vomiting, diarrhea, and neurosensory complaints. Results from the comparative randomized trial mentioned above show that although docetaxel is associated with less neuropathy, myalgia, and hypersensitivity than paclitaxel given every 3 weeks, febrile neutropenia, fluid retention, and skin reactions appear to occur more frequently with docetaxel.[161]

A new formulation of paclitaxel has been approved by the FDA. This protein-bound paclitaxel (Abraxane®) is covalently bound to albumin, then microemulsified into nanoparticles to improve solubility of the chemotherapeutic agent. In a randomized trial of protein-bound paclitaxel versus conventional paclitaxel (each given every 3 weeks), the protein-bound paclitaxel was associated with improved response rates and time-to-progression in patients with taxane-naive metastatic breast cancer.[162] Myelosuppression was more pronounced in the conventional paclitaxel arm, whereas peripheral neuropathy was more frequently observed in the protein-bound paclitaxel arm. Weekly administration of the protein-bound paclitaxel also has been reported to be efficacious and safe. Final results from phase III comparative studies with docetaxel or weekly conventional paclitaxel have yet to be reported. Many ongoing clinical trials will help to further elucidate the role of protein-bound paclitaxel in the clinical management of both metastatic and early breast cancer.

After patients have been treated with an anthracycline and a taxane, single-agent capecitabine, vinorelbine or gemcitabine have resulted in response rates of 20% to 25%.[163] Of these agents, only capecitabine is FDA approved as a single agent for metastatic breast cancer. Gemcitabine is only FDA approved in combination with paclitaxel for metastatic breast cancer. However, all of these are included in most national and international guidelines as appropriate therapy for metastatic breast cancer. Decisions regarding which agent to choose are based on patient characteristics, expected toxicities and previous exposure to chemotherapy. An increasing number of patients diagnosed with metastatic breast cancer have been exposed to adjuvant chemotherapy consisting of an anthracycline and a taxane. If metastases are found within 6 to 12 months of completing treatment with these agents, many clinicians will choose treatment from a different chemotherapy class. If it has been longer since their adjuvant therapy, then retreating with the same agents may be considered. However, given the cardiotoxicity associated with the anthracyclines, the use of these agents in the metastatic setting has been generally avoided until the availability of the liposomal anthracyclines. Pegylated liposomal doxorubicin is associated with less cardiotoxicity and similar efficacy compared to conventional doxorubicin and is a viable option for women who recur more than 1 year after their adjuvant anthracycline regimen.[164]

Anthracyclines, taxanes and capecitabine are all approved for metastatic breast cancer and have very specific indications for their use. Patients who initially respond to these classic agents progress later, are usually in fairly good health and have few effective options at this juncture in the course of their disease. One class of drugs that shows promise in this resistant population is the epothilones. Epothilones are natural compounds first identified

from soil-derived *Sorangium cellulosum* myxobacterium. They are classified as microtubule stabilizing agents (MSAs). The mechanism of action of the epothilones is similar to but distinct from the taxanes, binding to β-microtubulin in a unique manner but ultimately leading to microtubule stabilization and cell death in similar manner compared to the taxanes. These natural compounds are very lipophilic and unstable in solution, leading to development of semisynthetic analogues. One of these analogues, ixabepilone, has shown significant activity in patients with metastatic breast cancer who have received a taxane, anthracycline and capecitabine and is FDA approved in this setting. Single agent data with ixabepilone demonstrated a 22% to 57% objective response rate in patients who were heavily to minimally pretreated, respectively.[165] In combination with capecitabine, ixabepilone was found to increase response rates (35% vs 14%; P <0.0001) and time-to-progression (5.8 months vs 4.2 months; P = 0.0003) compared to capecitabine alone in metastatic breast cancer patients who had received a prior taxane and ananthracycline.[165] Ixabepilone is also FDA approved in combination with capecitabine for this indication as well. Adverse effects associated with ixabepilone include myelosuppression, peripheral neuropathy, myalgias/arthralgias, alopecia, mild nausea, and skin/nail changes.[165] Other epothilones are currently in clinical trials and could lead to significant advances in many other cancers.

Combination chemotherapy regimens are associated with higher response rates than are single-agent therapies in the treatment of metastatic breast cancer, but the higher response rates have not usually translated into significant differences in time-to-progression and OS. The use of sequential single-agent chemotherapies versus the combination regimens is widely debated for metastatic breast cancer.

One trial investigating the combination of doxorubicin with paclitaxel versus each single agent with crossover to the other agent upon progression set out to help answer the question of which approach is more effective.[166] While response rates were higher with the combination regimen, time-to-progression and OS were similar between all arms of the study. This was probably because most patients who progressed on their first single agent went on to receive the second-line single agent, thereby negating any potential survival benefits seen with improved response rates. In another study comparing single-agent docetaxel to the combination of docetaxel with capecitabine, the combination arm produced higher response rates, time-to-progression, and OS than did the single agent.[167] However, because only 15% of patients in the docetaxel-alone arm received capecitabine after progression, this study does not answer the question of whether combination therapy is better than sequential single-agent therapy. Other studies also have demonstrated similar results, but none of them adequately answer the question of whether sequential administration of single-agent chemotherapy or concurrent combination chemotherapy is optimal. Recently published international guidelines reflect this assertion with recommendations which favor sequential single agents over combination regimens unless the patient has rapidly progressive disease, life-threatening visceral disease, or the need for rapid symptom control.[168]

Combination regimens are associated with greater toxicity. In the palliative metastatic setting, the least toxic approach is preferred when efficacy is considered equal. In clinical practice, patients who require a rapid response to chemotherapy (e.g., those with symptomatic bulky metastases) often receive combination therapy despite the added toxicity. This decision is complex and should be made on an individual patient basis.

Biologic or Targeted Therapy

Therapies that focus on molecular targets through novel mechanisms are often referred to as biologic or targeted therapy. These agents, while using the biologic knowledge gained from decades of research, are designed to specifically target cancer cells while generally sparing normal tissues. For breast cancer, several agents that focus on a myriad of targets that are differentially expressed in breast cancer cells and play a critical role in their proliferation and survival are available in this class.

***HER2*-Targeted Agents** Trastuzumab and lapatinib are the only *HER2*-targeted agents currently available in the United States, while many others are under investigation. Trastuzumab is a humanized monoclonal antibody that binds with a specific epitope of the *HER2* protein. Mechanisms of action of trastuzumab include disruption of HER receptor dimerization, disruption of downstream signaling pathways (e.g., PI3K/Akt), G_1 arrest and reduced proliferation, induction of apoptosis, suppression of angiogenesis, induction of immune-mediated responses (e.g., antibody-dependent cellular cytotoxicity), inhibition of *HER2* extracellular domain proteolysis and inhibition of DNA repair. These biologic effects lead to inhibition of cellular growth, decreased malignant potential, and possibly reversal of resistance to certain chemotherapies and endocrine therapy. Single-agent treatment with trastuzumab has a response rate of 15% to 20% and a clinical benefit rate of nearly 40% in patients with *HER2*-overexpressing cancers.[169] Moreover, the results of a large randomized trial demonstrated that trastuzumab has at least additive, and perhaps synergistic, activity with other chemotherapeutic agents.[170] In this pivotal trial comparing chemotherapy in combination with trastuzumab versus chemotherapy alone, the addition of trastuzumab increased response rates, time-to-progression, and OS when compared to chemotherapy alone. Patients who were anthracycline naive were treated with an anthracycline (mostly doxorubicin, some epirubicin) plus cyclophosphamide, and patients who had received an adjuvant anthracycline regimen were treated with paclitaxel. During this trial, patients who received the anthracycline-trastuzumab combination had a very high incidence of cardiotoxicity (27%), leading to discontinuation of this arm of the study and a black box warning regarding this contraindication in the product information for trastuzumab. Many investigators are attempting to circumvent this toxicity while giving these two classes of agents together (e.g., liposomal doxorubicin, continuous-infusion doxorubicin, lower-dose epirubicin). However, until further information regarding the safety of these approaches becomes available, anthracyclines administered concurrently with trastuzumab should not be given outside the context of a clinical trial in patients with metastatic breast cancer.

Many other chemotherapy agents have successfully been administered with trastuzumab. Only two other phase III trials have been published comparing chemotherapy alone versus chemotherapy plus trastuzumab. Marty et al. compared docetaxel alone versus docetaxel with trastuzumab in patients with previously untreated *HER2*-positive metastatic breast cancer.[171] That trial demonstrated significant advantages to the combination over chemotherapy alone in terms of response rates, time-to-progression, and OS. von Minckwitz et al. randomized patients who were progressing on front-line trastuzumab-containing regimen to receive either capecitabine alone or capecitabine with continued trastuzumab therapy.[172] Median time-to-progression was 5.6 months with capecitabine alone and 8.2 months with capecitabine plus trastuzumab (HR, 0.69; 95% CI, 0.48-0.97; P = 0.034). While there were methodological problems with this trial (e.g., slow accrual led to early closure, open-label design, etc.), results support the decade-long clinical practice of continuing trastuzumab beyond progression, but raise other questions as to the comparative benefit with this approach versus a lapatinib-based regimen (see discussion below).

Other chemotherapy agents that have been evaluated in several phase II trials in combination with trastuzumab include vinorelbine, gemcitabine, and the platinum agents (cisplatin and carboplatin). In phase II trials, vinorelbine in combination with trastuzumab has shown very high response rates, even in heavily pretreated patients.[173] In another phase III trial, the triplet combination of paclitaxel, carboplatin, and trastuzumab was compared with paclitaxel and trastuzumab as dual therapy.[174] This study demonstrated superior response rates and time-to-progression with the triplet regimen versus the doublet regimen. A similar trial designed to confirm this data using docetaxel instead of paclitaxel failed to demonstrate any advantage with the addition of carboplatin to a taxane-trastuzumab regimen.[175] These conflicting results indicate that the benefit of adding a platinum compound to these regimens remains questionable. Toxicities with the addition of carboplatin are significantly greater in terms of myelosuppression and nausea, which should be considered when making treatment decisions in the setting of metastatic breast cancer where quality-of-life is paramount.

Significant cross-talk exists between the growth factor pathways (e.g., *HER2*) and the hormone receptor pathways (e.g., ER). This has generated a hypothesis that combining endocrine therapies with *HER2*-targeted therapies may be synergistic or at least additive in their anticancer effects. The TAnDEM trial randomized patients with HER2-positive MBC to anastrozole with or without trastuzumab.[176] The addition of trastuzumab improved PFS from 2.4 months to 4.8 months ($P = 0.0016$) and overall response rate and clinical benefit rate were also significantly improved. Many other trials are seeking to confirm this information. While confirming information is awaited, these combinations are frequently utilized in current clinical practice for patients with hormone-receptor-positive, *HER2*-positive metastatic breast cancer.

Trastuzumab is generally well tolerated. The most common adverse effects are infusion-related (primarily fever and chills), occur in approximately 40% of patients during the initial infusion and generally go unrecognized by patients. Other infusion-related reactions include mild nausea, pain at tumor sites, rigors, headaches, dizziness, hypotension, rash, and asthenia, which are much less common.[177] These reactions are generally mild to moderate and last about 1 to 2 hours after the infusion is started and usually do not recur with subsequent infusions. Acetaminophen and diphenhydramine may be given and/or the infusion rate reduced to help alleviate the symptoms related to these reactions. If infusion-related symptoms occur, subsequent doses should be infused over 90 minutes. Infusion over 30 minutes is appropriate if symptoms subside. A rare, but more severe reaction consisting of severe hypersensitivity and/or pulmonary reactions has been reported. It is important to educate patients regarding the pulmonary reactions, as these may occur up to 24 hours after the infusion and can be fatal if not promptly treated. Trastuzumab may increase the incidence of infection, diarrhea, and/or other adverse events slightly when given with chemotherapy, but most of these increases are not clinically significant for an individual patient.

The most serious adverse effect of trastuzumab is cardiotoxicity. As mentioned earlier, the incidence of heart failure is approximately 5% with single-agent trastuzumab and the risk is unacceptably high when trastuzumab is given with an anthracycline. Fortunately, heart failure seen with trastuzumab is somewhat reversible with pharmacologic management and some patients have continued therapy with trastuzumab after their left ventricular ejection fraction has returned to normal with medical management. Although there are no guidelines for cardiac monitoring with this agent, close monitoring for clinical signs and symptoms of heart failure is recommended in order to intervene with appropriate cardiac treatments.

Trastuzumab may be administered as an initial loading dose of 4 mg/kg, followed by a 2-mg/kg dose administered weekly or every 3 weeks utilizing a loading dose of 8 mg/kg followed by 6 mg/kg. Both of these dose/schedules are FDA approved. Every 3-week administration is more convenient than weekly administration, but comparative data with this dose schedule versus the weekly dose schedule are not available at this time. The schedule of chemotherapy often dictates which trastuzumab dosing regimen will be utilized. When patients progress on therapy with trastuzumab, many clinicians will continue the trastuzumab and change the chemotherapy regimen. With the capecitabine data (mentioned previously) now available, this practice seems effective and reasonable. This practice has changed with the availability of lapatinib, which is effective in trastuzumab-resistant disease (see below). However, upon progression on a lapatinib-containing regimen, clinicians often resume therapy with trastuzumab in combination with a different chemotherapy regimen. There are no data to support this practice, but in light of the other available evidence this approach also seems reasonable.

Lapatinib is a tyrosine kinase inhibitor that dually targets *HER2* and the epidermal growth factor receptor (EGFR or *HER1*). This small molecule works intracellularly to actively shut down the signaling pathway from these two receptors and thus inhibit cell growth and division. Lapatinib is an oral agent with modest activity against breast cancer as a single agent. In metastatic breast cancer patients as first-line therapy, response rates to single agent lapatinib have been reported to be 24% in one phase II study and were generally confined to a *HER2*-positive subset of patients. This benefit is similar to what is seen with single agent trastuzumab administered as first-line therapy for metastatic breast cancer. In combination with capecitabine in women with *HER2*-positive metastatic breast cancer who were previously treated with an anthracycline, a taxane, and trastuzumab, it improves response rates (22% vs 14%; $P = 0.09$) and time-to-progression (8.4 vs 4.4 months; HR, 0.49; 95% CI, 0.34-0.71; $P < 0.001$) as compared to capecitabine alone.[178] Based on this evidence, the FDA approved lapatinib in this setting only. In combination with paclitaxel as first-line therapy for metastatic breast cancer (*HER2*-positive and -negative), the addition of lapatinib did not appear to improve outcomes for patients with *HER2*-negative disease. However, for patients with *HER2*-positive metastatic breast cancer, the addition of lapatinib significantly improved time-to-progression, event-free survival, objective response rates and clinical benefit rate, although the *HER2*-positive patients on the paclitaxel/placebo arm did not receive any *HER2*-directed therapy.[179]

Lapatinib has also been combined with endocrine therapy in hopes of taking advantage of the cross-talk between the growth factor receptor and the hormone receptor pathways as mentioned previously. In a large, randomized phase III study, letrozole was administered with either lapatinib or placebo in hormone-receptor-positive patients with metastatic breast cancer (*HER2*-negative and -positive).[180] The addition of lapatinib in *HER2*-positive patients improved PFS from 3 months to 8.2 months (HR, 0.71; 95% CI, 0.53-0.96; $P = 0.019$). In *HER2*-negative patients, no significant benefit was observed with the addition of lapatinib. Another interesting approach to *HER2*-positive metastatic breast cancer has been to combine *HER2*-targeted agents with differing mechanisms of action. O'Shaughnessy and colleagues compared lapatinib alone to lapatinib plus trastuzumab in patients with metastatic breast cancer progressing on trastuzumab therapy. PFS was significantly improved with the combination (12 vs 8.4 weeks; $P = 0.029$).[181] However, the clinical significance of this small difference (less than 1 month) is debatable and the expense of this regimen is obvious.

Because lapatinib is a small molecule and can readily cross the blood-brain barrier, investigation has ensued to ascertain its effects

on brain metastases. Trastuzumab does not cross the blood–brain barrier and the central nervous system is often a sanctuary site for progressive metastases, representing the first site of recurrence in a relatively large number of patients. Phase II trials investigating the efficacy of lapatinib in patients with treated brain metastases failed to demonstrate any significant response. However, in the large randomized trial with capecitabine ± lapatinib, the addition of lapatinib was associated with a lower rate of the central nervous system as a site of first progression (2% with lapatinib vs 6% with capecitabine alone; $P = 0.045$).[178] Ongoing adjuvant trials with lapatinib will continue to evaluate this relationship and determine the value of lapatinib for prevention of central nervous system metastases.

Adverse events associated with the addition of lapatinib are primarily rash and diarrhea. These adverse effects appear to be more significant when combined with chemotherapy (e.g., capecitabine, paclitaxel), but are generally manageable with aggressive antidiarrheal therapy and/or dose reductions. Other rare effects have been reported (QT prolongation, hepatotoxicity, and interstitial lung disease) and patients should be counseled regarding these effects. Because of concerns regarding the role of *HER2* in normal cardiac functioning, lapatinib may also increase the risk for cardiac dysfunction. However, in a review of more than 3,689 patients who received lapatinib in phase I to III trials, cardiotoxicity occurred in only 1.6% of patients.[182] Although these data are reassuring, it does not rule out the possibility of expanded toxicity when this agent is used in patients not included in the clinical trials such as those with underlying cardiac risks. Drug–drug and/or drug–food interactions are particularly important with lapatinib due to its metabolism through the cytochrome P450 system (3A4) and other pharmacokinetic/pharmacodynamic issues. Many of the adverse effects listed previously may be exacerbated due to drug or food interactions and careful review of patients' medication lists and education regarding these issues are extremely important. Lapatinib is currently being investigated in numerous clinical trials, the results of which will further elucidate the role of this agent in the management of both early and late stages of the disease.

It should be noted that only 20% to 30% of patients with metastatic breast cancer overexpress *HER2*, and commercially available IHC tests that are reported as 2+ for *HER2* are often negative by the more sensitive and specific FISH technique. To date, there is no benefit associated with the administration of trastuzumab to patients with *HER2*-negative tumors (IHC score of 0 to 1+, or FISH-negative), and a very questionable benefit associated with administration of trastuzumab to women with tumors that are 2+ for *HER2* by IHC staining alone. The patients who benefit most from trastuzumab therapy include those whose tumors express *HER2* protein at the 3+ level or who clearly demonstrate gene amplification by FISH testing. Further analyses investigating what other predictive markers for response to trastuzumab and lapatinib may be clinically useful are currently ongoing.

Other Targeted Agents Targeting tumor blood vessels is another strategy to fight breast cancer. One of the most important growth factors that regulate the development of new blood vessels (angiogenesis) is vascular endothelial growth factor. Bevacizumab is a monoclonal antibody targeted against vascular endothelial growth factor and is FDA approved for use with chemotherapy for the management of a variety of malignancies. Bevacizumab has also been tested in clinical trials with capecitabine and paclitaxel in metastatic breast cancer patients. In the first clinical trial reported in breast cancer patients, bevacizumab was given every 3 weeks in combination with capecitabine in women who had failed both anthracycline- and taxane-containing regimens.[183] While response rates were significantly higher in the bevacizumab arm of this trial, time-to-progression and OS remained the same as with capecitabine alone. In a subsequent trial, newly diagnosed metastatic breast cancer patients were randomized to receive weekly paclitaxel with or without bevacizumab (given every other week).[184] That trial demonstrated significantly better response rates and time-to-progression with the addition of bevacizumab, but failed to demonstrate a survival benefit with the addition of bevacizumab. These two trials differed in their patient populations, choice of chemotherapy and bevacizumab dose and schedule. Other trials with bevacizumab include the AVADO trial, which randomized newly diagnosed metastatic breast cancer patients to docetaxel or docetaxel plus bevacizumab (both administered every 3 weeks).[185] This trial also demonstrated a similar although smaller advantage with bevacizumab in terms of PFS. Other clinical trials confirm the benefits of bevacizumab in combination with other chemotherapy agents (e.g., RIBBON I and II trials conducted in metastatic breast cancer patients as first-line and second-line therapy, respectively).[186,187] Adverse events attributable to bevacizumab in these combination regimens include hypertension, proteinuria (which can lead to renal tubular necrosis), thrombosis, bleeding, and cardiotoxicity. The addition of bevacizumab may also increase the incidence of neuropathy, fatigue and neutropenia associated with the chemotherapy. Based on these conflicting results, the relatively small differences in beneficial outcomes, and the questionable tolerability, the role of bevacizumab is not clearly defined for the management of metastatic breast cancer. Nonetheless, the NCCN has incorporated the bevacizumab/paclitaxel regimen into their guidelines as one option for the management of metastatic breast cancer and the FDA has approved its use with paclitaxel in the first-line setting.[47]

Many other biologic or targeted agents are being investigated and may end up changing the overall management of breast cancer for both early and metastatic disease.

Radiation Therapy

Radiation is an important modality in the treatment of symptomatic metastatic disease. The most common indication for treatment with radiation therapy is painful bone metastases or other localized sites of disease refractory to systemic therapy. Radiation therapy provides significant pain relief to approximately 90% of patients who are treated for painful bone metastases. Radiation is also an important modality in the palliative treatment of metastatic brain lesions and spinal cord lesions, which respond poorly to systemic therapy, as well as eye or orbit lesions and other sites where significant accumulation of tumor cells occurs. Skin and/or lymph node metastases confined to the chest wall area may also be treated with radiation therapy for palliation (e.g., open wounds or painful lesions). Chemotherapy may also be added to radiation for sensitization purposes.

PREVENTION AND EARLY DETECTION

Current efforts at breast cancer prevention are directed toward the identification and removal of risk factors often referred to as risk reduction strategies. Unfortunately, a number of risk factors associated with development of breast cancer, such as family history of breast cancer or personal history of breast or other gynecologic malignancies, cannot be modified. Isolation and cloning of breast cancer susceptibility genes now allows screening of women with histories suggestive of "breast cancer families" and identification of appropriate candidates for prophylactic bilateral mastectomies and/or bilateral salpingo oophorectomy. These surgeries are considered for women who are at very high risk for the development

TABLE 136-14 Current National Guidelines on Risk Reduction (Prevention) Strategies for Breast Cancer in Women Desiring Risk Reduction Therapy

Risk Category/Strategy	NCCN[42]	ASCO[189]
Average Risk		
Mastectomy[a]	Not recommended	Not addressed
Oophorectomy[b]	Not recommended	Not addressed
Tamoxifen[c]	Not recommended for women with: • Gail 5-year risk < 1.7%[f]	Not recommended for women with: • Gail 5-year risk < 1.66%[f] • Limited data women < 35 years old
Raloxifene[d]	Not recommended for women with: • Gail 5-year risk < 1.7%[f] • Premenopausal status	Not recommended for women with: • Gail 5-year risk < 1.66%[f] • Premenopausal status
High Risk		
Mastectomy[a,e]	Consider in the following women: • BRCA 1/2 carriers • Pedigree suggestive of genetic predisposition	Not addressed
Oophorectomy[b]	Limited to women with: • Known or strongly suspected BRCA 1/2 mutations	Not addressed
Tamoxifen[c,h]	Consider in the following women: • Prior thoracic RT or LCIS • Gail 5-year risk ≥ 1.7%[f] • Lifetime risk > 20% (using models based largely on family history)[g] • Pre- or postmenopausal	May offer to the following women: • LCIS • Gail 5-year risk ≥ 1.66%[f] • Pre- or postmenopausal
Raloxifene[d,h]	Consider in the following women: • Prior thoracic RT or LCIS • Gail 5-year risk ≥ 1.7%[f] • Lifetime risk > 20% (using models based largely on family history)[g] • ONLY postmenopausal	May offer to the following women: • LCIS • Gail 5-year risk ≥ 1.66%[f] • ONLY postmenopausal

NCCN = National Comprehensive Cancer Network; ACSO = American Society of Clinical Oncology; RT = radiotherapy; LCIS = lobular carcinoma in situ.

[a]Mastectomy = bilateral total mastectomy ± reconstruction.

[b]Oophorectomy = bilateral salpingo oophorectomy with peritoneal washings; pathologic assessment should include fine sectioning of the ovaries and fallopian tubes.

[c]Tamoxifen = 20 mg orally daily for 5 years.

[d]Raloxifene = 60 mg orally daily for 5 years; may continue for longer in women with osteoporosis.

[e]There are no data to support the use of pharmacologic risk reduction after bilateral mastectomies and the likely benefit would be very small, since the breast tissue at risk has largely been removed.

[f]The National Cancer Institute (NCI) Breast Cancer Risk Assessment Tool is a computer-based version of the modified Gail model and can be accessed via the NCI website (www.nci.nih.gov).

[g]Including but not limited to the Clause and BRCAPRO models.

[h]Contraindications to tamoxifen/raloxifene include: (1) history of thromboembolism (including venous thromboembolism, pulmonary embolism, thrombotic stroke, and/or transient ischemic attack); (2) pregnancy or pregnancy potential without adequate contraception. Endometrial hyperplasia has been reported with both agents; however, risk of endometrial cancer appears to be greater with tamoxifen. Therefore, adequate monitoring for gynecologic changes is paramount with both therapies.

of breast and/or ovarian cancer, particularly if the women's breasts are difficult to evaluate by both physical examination and mammography and if they have persistent disabling fears that they will be diagnosed with cancer. Guidelines for the incorporation of surgical risk reduction strategies are largely based on genetics and other known risk factors for development of breast (or ovarian) cancer (Table 136–14).

In the past 15 years, there has been increasing interest in pharmacologic risk reduction for breast cancer. Three important classes of agents being studied in this setting are the retinoids, SERMs, and aromatase inhibitors. Retinoids (all vitamin A and its isomer derivatives and synthetic analogs) are biologic regulators of orderly epithelial cell development, and are therefore potentially ideal agents for controlling abnormal epithelial proliferation that occurs in carcinogenesis. Because only preclinical data are available to suggest a benefit with these types of therapies, clinical trials are needed to further investigate the role of the retinoids in prevention of breast cancer.

The drugs with the most clinical information as risk reduction agents for breast cancer are the SERMs, tamoxifen and raloxifene. As previously described, tamoxifen is useful as an adjunct after treatment of primary breast cancer. In randomized trials of tamoxifen as an adjuvant treatment for breast cancer, women who received tamoxifen were also found to have a reduced incidence of contralateral primary breast carcinomas.[5] In a large, randomized, placebo-controlled study, the NSABP demonstrated significant reductions in risk of invasive and noninvasive breast cancers with 5 years of tamoxifen therapy (20 mg/day) in women at high risk for developing the disease.[55] Although this study is controversial, other studies from around the world also have been reported that investigated the role of tamoxifen as a risk reduction strategy. A meta-analysis of these trials indicates a consistent benefit with tamoxifen in reducing the incidence of ER-positive breast cancers (48% reduction; 95% CI, 36%–58%; P <0.0001).[188] Tamoxifen has been repeatedly shown to be a relatively safe drug with an acceptable toxicity profile when used to treat patients with breast cancer. However, its estrogenic effects on the uterus and the coagulation system increase the risk of serious adverse effects that may be critical for patients taking this agent as a risk reduction strategy. Toxicities associated with tamoxifen were previously described in the Adjuvant Endocrine Therapy section above. Any decision to use tamoxifen for risk reduction should be made after a thorough discussion of the woman's risk of breast cancer, the potential benefits of tamoxifen, and the potential serious adverse events associated with tamoxifen.

A second trial has been reported that compared tamoxifen to raloxifene in a similar population of high-risk women. The Study of Tamoxifen and Raloxifene (STAR or P2) was published in 2006 and demonstrated a similar rate of invasive breast cancers with the two drugs.[56] However, the rates of noninvasive breast cancer were numerically higher in the raloxifene arm of the trial, although this difference did not reach statistical significance. It is not clear what long-term outcome will be related to this difference, but further follow-up will be required to draw any sound conclusions. Rates of endometrial cancer and deep venous thromboses were more

frequent in the tamoxifen arm, but overall quality-of-life was similar between the two agents.[56] Based on these results, the FDA approved raloxifene for breast cancer risk reduction in women at high risk of the disease. A similar reduction in the incidence of contralateral primary breast cancers was demonstrated with anastrozole in the adjuvant ATAC study (discussed previously), leading to the premise that AIs may also play a role in risk reduction of breast cancer.[139] No data are yet available investigating the AIs in this setting, but clinical trials are underway.

The NCCN has established guidelines for risk reduction strategies, including mastectomy, oophorectomy, and/or pharmacologic agents.[54] These guidelines are based on risk assessment tools such as the Gail model, BRCAPRO, or Claus models (discussed earlier) as well as other established risk factors. Much of the guideline is dependent on a woman's wishes for intervention. The American Society of Clinical Oncology (ASCO) recently published recommendations guiding the use of the pharmacologic agents for breast cancer risk reduction.[189] These guidelines are similar to the NCCN guidelines in that they recommend the use of tamoxifen or raloxifene for postmenopausal women at high risk (as defined by the Gail or other models) and tamoxifen for premenopausal women at high risk based on the woman's wishes (Table 136–14).

⑩ The rationale for early detection of breast cancer is based on the relationship between stage of breast cancer at diagnosis and the probability for cure. If all breast cancer cases could be detected at a very early stage of the disease (i.e., small primary tumor and negative lymph nodes), then more patients theoretically could be cured of their disease. Screening guidelines for early detection of breast cancer in women at average risk have been developed by several organizations, including but not limited to the American Cancer Society (ACS), the United States Preventive Services Task Force (USPTF), and the NCCN.[42,190,191] The American Cancer Society guidelines are most commonly cited. However, it is important to note that the expert panels developing these guidelines often differ in their approach and analysis of the available data, as is evident in the controversies that currently exist.

The ACS currently recommends that all women 20 years and older be informed of the benefits and limitations of breast self-examinations (BSEs).[190] Several studies have investigated the benefits of BSE. These trials were primarily conducted prior to the routine use of mammographic screening and demonstrated an inferential benefit in diagnosis of earlier stages of breast cancer. One trial, the Shanghai trial, appeared to indicate no benefit, but there was a higher rate of biopsies in women who were taught BSE than in women who were not taught BSE.[192] The investigators from this trial caution that this was a study of BSE instruction and not BSE performance. Compliance and competency with the BSE were neither guaranteed nor evaluated in this trial. Because of the lack of direct evidence to support or refute a benefit with BSE and the apparent associated increase in biopsy rates, the ACS has taken the position that it is optional, but women of all ages should be encouraged to be aware of their breasts in order to recognize any changes and promptly report these to a health professional.[190] Other organizations have taken a similar approach to their recommendations regarding BSE or simply state that there are insufficient evidence to recommend this practice.

Recommendations for breast examination by a healthcare professional (clinical breast examination) vary among the screening guidelines most often cited. The rate of breast cancer detection using clinical breast examination (CBE) alone is low, with even lower rates in younger women and women with higher body weight.[190] Randomized clinical trials have reported inconsistent results and often evaluated CBE in conjunction with mammograms. The ACS recommends CBE in conjunction with mammography for women ages 40 years and older.[190] For younger patients (in their 20s and 30s), it is recommended as part of a periodic health examination every 3 years, but this recommendation is based on weak evidence. The USPTF concluded that there is insufficient evidence to assess the benefits/risks of CBE beyond screening mammography in women over the age of 40 years.

The most controversial screening recommendation for breast cancer is related to annual mammography. It is clear that screening mammography decreases mortality from breast cancer. The controversies surround the balance of benefits and harms associated with a less than perfect screening test in women at average risk of developing breast cancer but of differing ages. Multiple clinical trials have been completed over the years and multiple meta-analyses of these trials have been conducted as well. Most of the trials included women 50 to 74 years of age and the interval between testing ranged from 12 to 33 months. The most recent meta-analysis of these data estimated a "number needed to invite for screening to extend one woman's life" (NNI) as 1,339 for women aged 50 to 59 years.[193] Some trials also included women aged 40 to 49 years, albeit significantly fewer women in this age group were included in the meta-analyses. The estimated NNI for women aged 40 to 49 years was reported as 1,904. The largest benefit was found in women ages 60 to 69 years with an estimated NNI of 377. None of the trials included women 75 years of age or older, thus there are no data to support or refute the benefit of screening mammography in this population.[193]

Incorporation of this new information into national guidelines differs with each organization. The ACS continues to recommend annual screening mammography for women ages 40 and older (as long as they are in good health).[190] This recommendation allows for individualized decisions to be made based on the overall health of the woman, but does not limit access to younger or older women who may benefit from screening. The USPTF has taken a different approach, recommending against routine screening mammography for women ages 40 to 49 and 75 years or older.[191] These recommendations are based on the available evidence, but do not allow for individualization based on a woman's overall health and make an arbitrary judgment that the NNI of 1,904 for women 40 to 49 years is not acceptable compared to 1,339 for women aged 50 to 59 years. For women 50 to 74 years of age, the USPTF recommends biennial screening mammography. This interval recommendation was based on assumptions of risks and benefits based on the available studies. While the upper limit for screening varies among guidelines, most experts agree that mammograms in women over the age of 74 are not supported by the current body of evidence, but some women may benefit if they are otherwise in good health and have a life expectancy of 10 years or more. There are also many other debates within this controversial area and the reader is referred to these references for further details.[42,190,191,193]

Other radiologic methods of breast imaging are also being investigated (e.g., digital mammography, ultrasonography, and MRI) and minimal data exist to support these methods in some high risk populations. Recommendations for women with a high risk of breast cancer are not fully established and definitions of "high risk" vary between different guidelines. The ACS include breast screening MRI as an adjunct to mammography for the following groups of high-risk women: (1) known *BRCA* mutation carriers; (2) untested individuals with a first-degree relative with a *BRCA* mutation; (3) women with a 20% or greater lifetime risk of breast cancer based on models that largely depend on family history; (4) women who had radiation to the chest between the ages of 10 and 30 years of age; (5) women with LiFraumeni syndrome, Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome, or have a first-degree relative with one of these syndromes.[190,194] The NCCN also has adopted consensus guidelines for women at high risk of breast cancer, incorporating breast MRI with other established screening tools for women as young as 25 years old (Table 136–15).[42]

TABLE 136-15 Breast Cancer Screening Guidelines

Risk Category	ACS[189]	USPTF[190]	NCCN[54]
Average risk			
BSE	Age ≥20 y: optional (discuss benefits/limitations)	Not recommended	Age ≥20 y: breast awareness
CBE	Age ≥20–39 y: every 3 years Age ≥40 y: annually (as long as in good health)	Insufficient evidence	Age ≥20–39 y: every 1–3 years Age ≥40 y: annually
Mammography	Age ≥40 y: annually (as long as in good health)	Age 50–74 y: biennial	Age ≥40 y: annually
High risk[a,b]			
BSE	NA	NA	All ages: breast awareness
CBE	NA	NA	All ages: every 6–12 months
Mammography	Annually w/ MRI	NA	Prior RT or strong family Hx or genetic predisposition, age ≥25: annually (+ CBE) All other categories: annually (+ CBE)
Breast MRI	Annually w/ mammogram Consider in moderate risk women as well	NA	Consider annually w/ mammogram + CBE for: (1) prior RT, age ≥25 y; (2) lifetime risk >20%; (3) strong family history or genetic predisposition, age ≥25 y; (4) history of LCIS

ACS, American Cancer Society; USPTF, United States Preventive Task Force; NCCN, National Comprehensive Cancer Network; BSE, breast self-exam; CBE, clinical breast exam by a health care professional; MRI, magnetic resonance imaging; NA, not addressed; RT, thoracic radiation therapy; LCIS, lobular carcinoma in situ.

[a]High risk is defined by the ACS as women with (1) a known *BRCA1/2* gene mutation; (2) untested woman with first-degree relative with a known *BRCA1/2* gene mutation; (3) lifetime risk of breast cancer of 20%–25% or greater using a risk assessment tool based largely on family history; (4) radiation therapy to the chest between the ages of 10 and 30 years; (5) LiFraumeni syndrome, Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome, or have first-degree relatives with one of these syndromes. Moderately increased risk is defined as a woman with (1) a lifetime risk of breast cancer of 15%–20% using a risk assessment tool based largely on family history; (2) personal history of breast cancer, DCIS, LCIS, or AH; (3) extremely dense breasts or unevenly dense breasts when viewed by mammograms.

[b]High risk is defined by the NCCN as women with (1) prior thoracic radiation therapy; (2) 5-year risk of ≥1.7% of invasive breast cancer in women ≥35 years old; (3) lifetime risk of >20% as defined by models that are largely based on family history; (4) strong family history or genetic predisposition; (5) LCIS/atypical hyperplasia; (6) prior history of breast cancer.

It should also be noted that there are risks associated with any screening procedure and they should be discussed with each patient so they are able to make an informed decision regarding these procedures. The risks involved with screening mammograms include false-negative results, false-positive results, overdiagnosis (true positives that will not become clinically significant), and radiation risk. The rate of false-negative results with the current technology is approximately 20%, which explains why CBE is an important adjunct to screening for many women. Although the specificity of mammography is quite high (90%), most abnormal examinations are false positives, leading to additional biopsies and psychological distress. The issue of overdiagnosis refers primarily to the growth in detection of DCIS from screening mammography. The biologic significance of these tumors is unknown because only some of them would become invasive if left in place. So the question remains: Are we treating women who do not require treatment? Experts in the field continue to debate this issue. Radiation exposure also has been discussed in the context of screening mammography, but the small doses of radiation exposure with mammograms (2 to 4 mGy [0.2 to 0.4 Rad] per standard two-view examination) appears to be overshadowed by other benefits in terms of reduction in mortality as a consequence of early cancer detection.[191]

Significant advances in the safety and efficacy of screening mammography have occurred during the past two decades. These advances have enabled superior visualization of breast and breast tissue with a lower dose of radiation being delivered. Despite these advances, approximately 10% of all palpable masses are not detected by mammography. This is most commonly observed in premenopausal women, and may be directly related to the increased density of breast tissue in this estrogen-rich environment.

Although the safety and efficacy of screening mammography in terms of image quality and dosimetry are very acceptable, the need for greater quality control in mammography was recognized for some time. The Mammography Quality Standards Act (MQSA) of 1992 assures that all mammographic facilities achieve a common high standard of quality assurance. Responsibility for operation of the act was given to the FDA and all facilities that offer mammography must be FDA certified to remain open. The MQSA has now been updated to also include full field digital mammography as well, although the use of this new technology has not yet been incorporated into national screening guidelines. Passage of this landmark legislation, as well as provision of appropriate levels of funding to conduct this program, represents an important contribution to the health of women. Similar quality assurance measures will need to be implemented for breast MRIs and ultrasonography, given the recommendations to utilize these imaging methods for early detection and diagnosis, respectively, in high-risk women and those with suspicious masses. All women should be aware that breast MRIs and ultrasounds are not currently regulated and should choose to have these tests performed at a reputable facility to insure quality. The American College of Radiology has developed reporting guidelines to standardize the way these images are interpreted. These are referred to as the Breast Imaging Reporting and Data System (BI-RADS) and are available for mammography, breast ultrasonography and breast MRIs.[43] This reporting method allows for uniformity between facilities and better comparisons over time. Nonetheless, differences remain between breast imaging quality and interpretation and it is best to have imaging conducted at the same facility over time if possible.

EVALUATION OF THERAPEUTIC OUTCOMES

9 The desired therapeutic outcome of adjuvant therapy of breast cancer differs significantly from that of metastatic disease. Adjuvant therapy—chemotherapy, biologic therapy, and hormonal therapy—is administered with curative intent. The rationale for adjuvant therapy is that breast cancer, even when diagnosed in early stages when clinical evidence of distant spread is not apparent, is a systemic disease that spreads early to distant sites. Adjuvant therapy is intended to eradicate micrometastases and thus cure the patient of breast cancer. Therefore, the overall goal of adjuvant therapy is to cure the disease, which is something that cannot be fully evaluated for years following initial diagnosis and treatment. In addition, because disease cannot be detected at the time adjuvant therapy is started, assessment of disease response is not possible. Instead, a predetermined number of cycles of adjuvant therapy and/or years of biologic or hormonal therapy are administered. Adjuvant chemotherapy is often associ-

ated with significant toxicity. Maintaining dose intensity has been demonstrated to be important in the cure of disease, and therefore optimizing supportive care measures such as antiemetics and growth factors is highly recommended. The concept of dose density, using growth factors to maintain blood counts while decreasing the interval between chemotherapy administrations, is very controversial in the management of early-stage breast cancer. Multiple studies investigating this approach to adjuvant chemotherapy have been conducted with conflicting results and many more trials continue to be analyzed in hopes of determining the long-term outcomes related to this approach to therapy. The goals of therapy with neoadjuvant chemotherapy are slightly different. These goals focus on earlier end points of tumor response so as to minimize surgery, determine prognosis, and potentially conserve the breast tissue for a better cosmetic result. The other outcomes discussed with adjuvant therapy also apply to this scenario, in terms of improving survival and decreasing recurrences as compared to no systemic therapy.

Palliation is the therapeutic outcome in treatment of metastatic breast cancer. In general, the least-toxic therapies are used initially, with increasingly aggressive therapies applied in a sequential fashion and in a manner that does not significantly compromise the quality of the patient's life. Tumor response to a particular treatment regimen may be measured by clinical chemistry such as liver enzyme elevation in a patient with hepatic metastases or tumor markers, or imaging techniques such as bone scans or chest radiographs. However, assessment of the patient's clinical status and symptom control is often adequate to evaluate response to the therapy administered. In the patient with metastatic breast cancer, it is common to initiate hormonal therapy or chemotherapy and continue administration until signs and symptoms of disease progression or new signs and symptoms present. Optimizing quality-of-life is the therapeutic end point in the treatment of patients with metastatic breast cancer. A number of valid and reliable tools are available for objective assessment of quality-of-life in patients with breast cancer.

CONCLUSIONS

Breast cancer is the most commonly occurring cancer in women in the United States, and is second only to lung cancer as the most common cancer cause of death. The etiology of breast cancer is unknown, but a number of factors that increase a woman's chances of developing the disease have been identified. These risk factors suggest a complex interplay between hormones, genetic factors, environment, and lifestyle. The identification of the *BRCA1* and *BRCA2* genes, tumor suppressor genes important in the development of inherited and perhaps sporadic breast and ovarian cancer, has been instrumental in identifying patients who are at high risk, as well as improving our basic understanding of the causes of breast and ovarian cancer.

Most breast cancers are diagnosed in early stages before the disease has disseminated to sites distant from the breast. Treatment of early-stage breast cancer consists of local management, as well as systemic adjuvant therapy with chemotherapy, biologic and hormonal therapy, or a combination of these. BCT, which consists of complete removal of the tumor (lumpectomy), combined with breast irradiation and axillary lymph node staging, is currently the preferred method of treatment for most patients with localized breast cancer. Patients who are not candidates for breast conservation or who do not choose this local therapy will generally receive a modified radical mastectomy.

It is apparent from clinical and laboratory experiments and observation that spread of breast cancer via the bloodstream occurs early in the course of the disease, which can result in patients relapsing with systemic metastatic disease following local curative therapy. The likelihood of later development of metastatic disease is related to the size of the primary tumor, presence of lymph node involvement and number of nodes affected, and a number of additional pathologic prognostic factors, which include proliferative capacity, nuclear grade, hormone receptor status, and presence or absence of oncogenes and other protein products. Systemic adjuvant therapy is commonly administered to patients with localized breast cancer following surgical procedures to diminish the risk of or delay disease recurrence. The NCCN and other groups have developed guidelines for adjuvant systemic therapy for early stage breast cancer based on expert consensus and evidence, and these treatment recommendations continue to evolve as new data become available.

Advanced breast cancer includes locally advanced breast cancer (stage III) and metastatic breast cancer (stage IV). Treatment of stage III breast cancer generally consists of a combination of surgery, radiation, and chemotherapy administered in an aggressive approach. Although response rates and survival have improved, there is still much progress to be made in stage III breast cancer. Metastatic breast cancer is usually incurable with available therapies, and patients should be encouraged to participate in clinical trials of novel agents or therapeutic approaches. It is interesting to note that some long-term responses have been observed in a subset of patients with metastatic disease who have a complete or near complete response to conventional chemotherapy. Unfortunately, this represents a small number of the total population of patients with metastatic breast cancer. Metastatic breast cancer is treated with endocrine therapy, chemotherapy or biologic therapy depending on receptor status. Patients who are hormone receptor-positive will generally receive initial endocrine therapy followed by chemotherapy when endocrine therapy fails. Patients who are hormone receptor-negative or who have symptomatic disease involving the liver, lung, or central nervous system will generally receive chemotherapy as first-line therapy of metastatic disease. Chemotherapy will result in an objective response in approximately 50% to 60% of patients previously unexposed to chemotherapy. Most patients have partial responses, and complete disappearance of disease occurs in fewer than 10% of patients treated. Median duration of response is 5 to 12 months; although some patients will have an excellent response to an initial course of chemotherapy and may live 5 to 10 years without evidence of disease. In general, median survival of patients after treatment with commonly used drug regimens for metastatic breast cancer ranges from 14 to 33 months. The response rate to second- and third-line chemotherapy varies from 20% to 40%, depending on the previous chemotherapy regimens the patient has received. Development of novel targeted agents (e.g., trastuzumab, lapatinib) has also changed the outlook for patients whose tumors overexpress *HER2*. Through continued research, other biologic or targeted agents may also improve outcomes for breast cancer patients.

Current efforts at breast cancer prevention are directed toward the identification and removal of risk factors and risk reduction with surgery or drug therapy. Three classes of agents, the retinoids, SERMs, and AIs, are being evaluated for their ability to reduce the risk of breast cancer. Tamoxifen and raloxifene have demonstrated efficacy in decreasing rates of invasive breast cancer in women who are at high risk of developing the disease. Early detection of breast cancer remains important for decreasing breast cancer mortality. The rationale for early detection of breast cancer is based on the clear relationship between stage of breast cancer at diagnosis and the probability of a cure. The ACS and other groups have developed screening guidelines for early detection of breast cancer. Although these guidelines differ, the overall benefits of screening mammography are apparent in their recommendations. Incorporation of newer screening methods (e.g., MRI) into these guidelines has occurred and will continue to evolve as new data become available.

Intensive research efforts are ongoing in all aspects of breast cancer etiology, detection, prevention, and treatment. Thanks to the thousands of patients who volunteered for these clinical trials, a substantial reduction in mortality has been seen in select patient subsets. It is hoped that the information obtained in the next decade will result in the knowledge required to significantly reduce mortality from breast cancer for all women. Only through these continued efforts and participation of patient volunteers will advances be made in the management of this disease.

ABBREVIATIONS
